IP-122-1

As described in detail in Section 3.3.2.3 of the Recirculated Draft EIR/Supplemental Draft EIS, the revised build alternatives have been redesigned to avoid the need to relocate the Shelter Partnership's S. Mark Taper Foundation Shelter Resource Bank in the City of Bell under at least one build alternative. Under Alternative 5C, a partial acquisition would occur along the western portion of the property. It is possible that the redesign of the loading docks/zones, driveway areas, and traffic circulation patterns in the area could be done to avoid a relocation of the Resource Bank under Alternative 5C and retain the interrelated operational nature of the Bell Shelter and the Resource Bank. No relocation of the Bell Shelter would occur under Alternative 5C. Because Alternative 7 entails the addition of a separate freight corridor structure, and this location is constrained in terms of right of way due to the nearby utility corridor, Los Angeles River, and rail lines, impacts to the Bell Shelter/Resource Bank were unable to be avoided under Alternative 7. Specifically, Alternative 7 would require the acquisition/displacement of Bell Shelter's transitional housing structures, and the full acquisition and relocation of the Resource Bank. Please see Section 3.3.1 of the Recirculated Draft EIR/Supplemental Draft EIS for an updated discussion of community facilities, including the S. Mark Taper Shelter Resource Bank in the City of Bell.

IP-122-2

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-3

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-4

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-5

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-6

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-7

This comment expresses concern about potential access impacts to the S. Mark Taper Shelter Resource Bank during construction of the I-710 Corridor Project. Access to all properties in the Study Area will be maintained through implementation of the TMP described in Section 3.24.4 of the Recirculated Draft EIR/Supplemental Draft EIS.

IP-122-8

This comment expresses concern about potential air quality impacts to the S. Mark Taper Shelter Resource Bank during construction of the I-710 Corridor Project. Air quality construction impacts and mitigation is discussed in Section 3.24.3.13 of the Recirculated Draft EIR/ Supplemental Draft EIS.

IP-122-9

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-10

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-11

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-12

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-13

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-14

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-15

This comment requests consideration of a number of mitigation measures related to the S. Mark Taper Shelter Resource Bank in the City of Bell. Environmental justice mitigation measures have been incorporated into the RDEIR/SDEIS; please see Section 3.3.3 for more detailed information. Caltrans will work with Shelter Partnership to continue to refine the design near the Resource Bank to be as least impactful as is feasible.

IP-122-16

This comment requests a ventilation system be installed at the S. Mark Taper Shelter Resource Bank. Although not proposed as specific mitigation for the I-710 Corridor Project, such as system would be eligible for funding under the Community Health and Benefit grant program that is included under both proposed build alternatives and described in Section 2.3.2.1 of the Recirculated Draft EIR/Supplemental Draft EIS.

IP-122-17

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives.

IP-122-18

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives. With regard to the request to include the low-income and minority populations served by the S. Mark Taper Shelter Resource Bank in the environmental justice analysis in the EIR/EIS, all low-income and minority populations within the Study Area have been considered in the environmental justice analysis.

IP-122-19

As noted above in Response to Comment IP-122-1, impacts to the Bell Shelter and the S. Mark Taper Shelter Resource Bank in the City of Bell have been avoided/minimized in the design of one of the revised build alternatives. The updated information and analysis of any impacts to the S. Mark Taper Shelter Resource Bank have been addressed in this Recirculated Draft EIR/Supplemental Draft EIS.

From: Chaves, Ernesto
To: Rose, Kristin; Brown, Julia; Ruth Schwartz; Rhonda Villanueva; Horowitz, David I.; Ozurovich, Allie Kathleen
Subject: RE: I710 Corridor Project - Meeting with Shelter Partnership
Date: Thursday, October 5, 2017 2:41:21 PM

Kristen et. al,

As a follow up to our meeting yesterday, here are a couple of items:

1. The Noise Study Report (2016) can be found here: http://www.dot.ca.gov/d7/env-docs/docs/710corr-eir/Technical%20Studies/Noise%20Study%20Report%20May%202016.pdf. This is the report that documents the noise analysis done for the 710 Project. As you will see in Page 139 of the report, there are no proposed soundwalls in the vicinity of the Shelter Partnership because there were no sensitive receptors identified in this area and therefore no noise readings were taken. As we discussed, this is something you can point out in your comment letter and we will follow up.
2. I checked into the language of IP-122-1 in the Response to Comments of the 2012 DEIR/DEIS. What's described is a partial acquisition of the parcel, so essentially a sliver of parcel to accommodate the ramp. The reason the language also makes reference to redesigning driveways and docks is because we didn't know if that sliver would compromise any of the operations of the facility. If for some reason a configuration of the facility is required, then that would be covered under this document. Just to confirm, the building itself is not impacted.

Let me know if you have any other questions.

Thanks,

Ernesto Chaves

Subject: I710 Corridor Project - Meeting with Shelter Partnership
When: Wednesday, October 04, 2017 1:00 PM-2:00 PM (UTC-08:00) Pacific Time (US & Canada).
Where: Kirkland & Ellis - 333 South Hope Street, 29th Floor, Los Angeles CA 90071

Calendar reminder for our meeting on Wednesday October 4.

Location:
KIRKLAND & ELLIS LLP

333 South Hope Street, 29th Floor, Los Angeles, CA 90071

Parking:
If you choose to park in the building, please enter the parking garage from Hope Street, near the intersection with 3rd. Please take your parking ticket with you and we will provide validation.

The information contained in this communication is confidential, may be attorney-client privileged, may constitute inside information, and is intended only for the use of the addressee. It is the property of Kirkland & Ellis LLP or Kirkland & Ellis International LLP. Unauthorized use, disclosure or copying of this communication or any part thereof is strictly prohibited and may be unlawful. If you have received this communication in error, please notify us immediately by return email or by email to postmaster@kirkland.com, and destroy this communication and all copies thereof, including all attachments.

IP-35-1

Caltrans and Metro thank the commenter for their input. The commenter's support of Alternative 5C and opposition to Alternative 7 are acknowledged and included in the project record. However, Caltrans, as lead agency under CEQA and NEPA (as assigned by the Federal Highway Administration [FHWA]), in cooperation with the Los Angeles County Metropolitan Transportation Authority (Metro), has identified Alternative 1 (No Build) as the Preferred Alternative. Please refer to Section 1.1 of this appendix for a discussion on the identification of the Preferred Alternative.

IP-35-2

As noted in the comment, Alternative 5C would require a partial acquisition of the property and Alternative 7 would require a full acquisition of the property associated with the S. Mark Taper Foundation Shelter Resource Bank. The commenters concern that the acquisitions would reduce or suspend operations of the S. Mark Taper Foundation Shelter Resource Bank is acknowledged and noted in the public record. The acquisitions at this property are discussed in Table 3.3-8 in Section 3.3.1 of the RDEIR/SDEIS, as well as being detailed in the tables and depicted on Sheet 30 Figures L-1 and L-2 in Appendix L, Parcel Acquisitions Under Alternatives 5C and 7, of the Final EIR/EIS. As discussed in the RDEIR/SDEIS, Alternative 1 (No Build) has been identified as the Preferred Alternative, which will not displace the Bell Shelter or S. Mark Taper Foundation Shelter Resource Bank.

IP-35-3

As discussed in Response to Comment IP-35-2, above, Alternative 1 (No Build) was identified as the Preferred Alternative and will not require relocation of the S. Mark Taper Foundation Shelter Resource Bank.

IP-35-4

Please refer to Response to Comment IP-35-2 regarding the relocation of the S. Mark Taper Foundation Shelter Resource Bank.

IP-35-5

Please refer to Response to Comment IP-35-2 regarding the relocation of the S. Mark Taper Foundation Shelter Resource Bank.

IP-35-6

Caltrans and Metro acknowledge that construction-related impacts may occur as a result of the build alternatives, which are described in more detail in Section 3.24 of this Final EIR/EIS. However, the build alternatives propose Measure CON-TR-1 which would provide for the preparation of a TMP, which, should a build alternative be selected as the Preferred Alternative, would include public outreach, including information on current and upcoming construction activities, lane and other closures, detours, and other information to assist residents, students, visitors, and business patrons to more effectively travel around and in the vicinity of active construction areas. However, as stated in Response to Comment IP-35-1, the No Build Alternative has been selected as the Preferred Alternative and therefore, no construction-related impacts will occur.

IP-35-7

Potential construction-related impacts resulting from the build alternatives, including air quality, were discussed in Section 3.24 of the RDEIR/SDEIS. Avoidance and mitigation measures proposed for the build alternatives for construction-related air quality and noise impacts are specifically located in Sections 3.24.4.13 and 3.24.4.14 of this Final EIR/EIS. In addition, as a non-profit organization, Shelter Partnership may be eligible for Community Health Benefit Program funding, which is a programmatic element of the build alternatives. The Community Health Benefit Program would aim to provide funding for projects intended to improve air quality and public health, of which air filtration/HVAC installation is considered eligible. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more information regarding the Community Health Benefit Program.

IP-35-8

Please refer to Response to Comment IP-35-7 for more detailed information regarding the Community Health Benefit Program. Because the S. Mark Taper Foundation Resource Bank acts as a warehousing facility, there is no Noise Abatement Criteria applicable to this facility (which falls into activity category F), and noise abatement is not considered for structures of this type.

IP-35-9

Please refer to Response to Comment IP-35-2 regarding the relocation of the S. Mark Taper Foundation Shelter Resource Bank.

IP-35-10

Shelter Partnership's preference of Alternative 5C because the S. Mark Taper Foundation Shelter Resource Bank would not be impacted under Alternative 5C is acknowledged and noted in the public record. Potential relocation impacts to the S. Mark Taper Foundation Shelter Resource Bank as a result of the build alternatives were analyzed and disclosed to the public in Section 3.3.1, Community Character and Cohesion, of the RDEIR/SDEIS. Please refer to Response to Comment IP-35-2 regarding the relocation of the S. Mark Taper Foundation Shelter Resource Bank.

IP-35-11

Please refer to Section 1.5 of this appendix regarding impacts to the Bell Shelter.

IP-35-12

Caltrans and Metro both respectfully disagree that the RDEIR/SDEIS fails to provide adequate assurances that the relocation plan proposed for the build alternatives complies with the requirements of the Uniform Act. As discussed in Section 3.3.2, Relocations and Real Property Acquisition, of the RDEIR/SDEIS, property acquisition and relocation should a build alternative be selected as the Preferred Alternative, relocations would be handled in accordance with the Federal and State laws (the Uniform Relocation Assistance and Real Property Acquisition Policies Act of 1970, as amended, also known as the Uniform Act, and California Government Code, Chapter 16, Section 7260, et seq.). Details of the Caltrans Transportation Relocation Assistance Program were provided in Appendix D of the RDEIR/SDEIS. Caltrans complies with this program, and with the requirements of the Uniform Act, on all projects. However, as stated in Response to Comment IP-35-1, the No Build Alternative has been selected as the Preferred Alternative and therefore, there will be no acquisitions or relocations.

IP-35-13

Although the S. Mark Taper Foundation Shelter Resource Bank serves a noble purpose in providing support to homeless services organizations throughout Los Angeles County, under the Caltrans Traffic Noise Analysis Protocol, it is not considered a noise-sensitive land use, as it does not have an exterior area of frequent human use. An area of frequent human use is defined as an area where people are exposed to traffic noise for an extended period of time on a regular basis. Also in accordance with the Protocol, noise abatement is only considered where frequent human use occurs and where a lowered noise level would be of benefit. Please also refer to Response to Comment IP-35-8 regarding the Community Health Benefit Program.

IP-35-14

Please refer to Response to Comment IP-35-13 regarding noise abetment at the S. Mark Taper Foundation Shelter Resource Bank.

IP-35-15

As a non-profit organization, Shelter Partnership is an eligible applicant for Community Health Benefit Program funding, of which air filtration/HVAC installation would be considered an eligible project. Shelter Partnership is encouraged to apply for funding through the Program to implement these types of improvements. However, as stated previously, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more information regarding the Community Health Benefit Program. In addition, since the No Build Alternative has been selected as the Preferred Alternative and no construction will occur, the S. Mark Taper Foundation Shelter Resource Bank will not experience air quality impacts during construction.

IP-35-16

Please refer to Response to Comment IP-35-6 regarding construction-related impacts to the S. Mark Taper Foundation Shelter Resource Bank.

IP-35-17

Caltrans and Metro respectfully disagree that the RDEIR/SDEIS is inadequate because it fails to analyze the Shelter Partnerships ability to comply with the Department of Health and Human Services' condition that the Shelter Partnership continuously use the property for public health purposes. The purpose of the RDEIR/SDEIS is to analyze environmental and social impacts related to the implementation of a transportation project. The RDEIR/SDEIS also discloses the Caltrans relocation process, which includes coordination with both the owner and occupants of displaced properties, both of who are eligible for relocation compensation and benefits. The Department of Health and Human Services' interest in the property does not change the environmental impacts, proposed avoidance, minimization, and/or mitigation measures for the build alternatives, and conclusion of the RDEIR/SDEIS related to the potential acquisition of the S. Mark Taper Foundation Shelter Resource Bank property resulting from the build alternatives.

Subject: I-710 Corridor Project Feedback

From: Clara Solis
Organization:
Phone: 3234226446
Mailing Address:
City, State:
Zip:
Comment/Question:
These comments are made in addition to my previous comments:

Current noise pollution from the I-710 should be reduced or not be increased by the project that is selected. Sound walls must be provided if they reduce the sound level even if the reduction is not to acceptable levels. If the sound walls do not decrease the noise to acceptable levels the noise pollution must be reduced by other means such as taller or better sound walls, landscaping, quieter road materials, soundproofing and retrofitting of all dwellings affected including but not limited to: schools, homes, public buildings, Churches and businesses. IP-36-1

Sound Wall SW519 should be built. Mitigation must be provided to reduce the increase in noise to the no build levels. IP-36-2

The visual impacts from Options 3A/3B are significant and unacceptable. The elevated SR 60 will loom over residents. It will change the way East Los Angeles residents feel about their community. It will become the predominant view for residents on Burger. East Los Angeles Option 3A/3B should be rejected. IP-36-3

*You received this message because Clara Solis submitted feedback regarding the I-710 Corridor Project.

Regards,
System Administrator

This page intentionally left blank

IP-36-1

Caltrans has analyzed the traffic noise impacts of the build alternatives at all noise-sensitive receptors and recommended reasonable and feasible noise abatement, based on State and Federal requirements and policies. However, it is important to note that Caltrans is not required to decrease noise levels to a certain level of acceptability. The potential for interior noise impacts has also been considered at those qualifying noise sensitive land uses as defined by the Caltrans Traffic Noise Abatement Protocol. No interior noise impacts from the build alternatives have been identified at any of the activity categories listed on Table 3.14-1 in Section 3.14.1.2 of this Final EIR/EIS. Residences are not considered a qualifying land use for interior noise impacts, per the Protocol. Currently, quieter pavement is not listed as a noise abatement measure for which Federal funding may be utilized.

IP-36-2

As discussed in further detail in Section 3.14.5.8 of this Final EIR/EIS, SW-519 was deemed both acoustically feasible and cost-reasonable, and was therefore recommended for construction, should a build alternative be selected as the Preferred Alternative. However, Caltrans, as lead agency under CEQA and NEPA (as assigned by the Federal Highway Administration [FHWA]), in cooperation with the Los Angeles County Metropolitan Transportation Authority (Metro), has identified Alternative 1 (No Build) as the Preferred Alternative. As a result, that particular soundwall was only necessary with implementation of Design Option 3A, which is no longer under consideration. Please refer to Section 1.1 of this appendix for further discussion on the identification of the Preferred Alternative.

IP-36-3

The commenter’s opposition to Design Options 3A and 3B are acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative, and Design Option 3A has been withdrawn from further consideration. Please refer to Section 1.1 of this appendix for further discussion on the identification of the Preferred Alternative.

Mr. Ronald Kosinski
Caltrans District 7, Division of Environmental Planning
100 South Main Street, MS 16
Los Angeles, CA 90012

Dear Mr. Kosinski,

DRAFT ENVIRONMENTAL IMPACT REPORT/
ENVIRONMENTAL IMPACT STATEMENT (EIR/EIS)
I-710 CORRIDOR PROJECT

Thank you for considering all of the comments included in this letter. Please consider seriously how much the community of East Los Angeles has suffered because of the impacts from the I-710 and all of the other freeways that run through it and around it.

Each of the issues and problems described in these comments should be addressed not only upon the issue raised but also as an environmental justice issue and as a violation of CEQA and NEPA standards. East Los Angeles is 97 percent Latino/Hispanic and a greater number of ELA residents are living below the poverty level than in Los Angeles County as a whole. A greater percentage of East Los Angeles residents live below the poverty level than in the study area. Additionally, East Los Angeles residents have a greater percentage of Latino/Hispanic residents than the percentage in the study area. IP-37-1

The 2017 Recirculated Draft EIR/EIS is deficient, it should be withdrawn and re-done and recirculated. East Los Angeles Option 3A/3B should be not be included in the redrawn EIR/EIS. Community Alternative 7 should be included for study. Caltrans should abide by Motion 22.1. Community input from East Los Angeles residents should be obtained regarding any options or alternatives impacting East Los Angeles prior to inclusion in the redrawn EIR/EIS. IP-37-2

If this project should go forward, we request mitigation for each and every one of the items brought up in all of this comment letter.

All of the issues raised unless otherwise stated are specific to the unincorporated area of East Los Angeles.

ENVIRONMENTAL JUSTICE

East Los Angeles is an environmental justice community. Ninety-Seven percent of the community is Latino. The percentage of Latinos in East Los Angeles far exceeds the numbers in the study area and in the County as a whole. The number of residents living below the poverty level exceeds the number of residents living below the poverty level in the study area. East Los Angeles is one of the most impoverished areas in the study area and is one of the areas with the highest number of Hispanic/Latinos in the study area.

SUPPRESSION OF THE ABILITY OF EAST LOS ANGELES RESIDENTS TO PARTICIPATE FULLY IN THE 2017 DRAFT EIR/EIS PROCESS

There seems to be an intentional attempt to suppress the ability of the East Los Angeles community to participate in the EIR/EIS process. The document was once again released in the summer and did not give sufficient time for residents to be informed and participate in the project. This same exact comment was made in 2012. Yet, here we are again. The staff and consultants had years to prepare this document but only 90 days were given to residents to become aware of the project, review the 10,000 plus page document and make comments. The 2010 US Census reports that fully 87.6 percent of the residents of East Los Angeles speak a language other than English at home compared to the California number of 43.6 percent, yet the majority of materials were in English. Additionally, many residents did not even learn of the project until October 18th when Los Angeles County Supervisor Solis held a community forum in East Los Angeles. Despite repeated attempts from residents and their elected officials to obtain a full 120 comment period, Caltrans refused. See attached letter of Congresswoman Lucille Roybal-Allard. There are also many errors in the document which make it difficult for East Los Angeles residents to fully understand what the ↓

IP-37-3

IP-37-4

IP-37-5

IP-37-6

impacts of this project are. Some of these errors include: Appendix L, an acquisitions page which says "Los Angeles" instead of East Los Angeles when describing the properties to be acquired and which lists residential properties as being Industrial, underestimates of the number of homes to be acquired listing 19 units instead of 24, underestimates the number of people to be displaced, 76 rather than 98, improperly lists a 10 unit apartment building as having 5 units, misidentifies East Los Angeles as the City of Los Angeles, and states that there are an adequate number of replacement homes for East Los Angeles residents. When the document was first released, the link to the comments section was not easily found. It was not until repeated phone calls and the advocacy of East Los Angeles elected officials that the comment link was moved to a location more easily found. Additionally, the link to the main pdf was not operating properly for the majority of the comment period. Finally, people submitting comments are not able to submit pdf files online. All of this left the residents of East Los Angeles unable to fully participate in the Recirculated Draft EIR/EIS process.

IP-37-6

IP-37-7

IP-37-8

ALL OF EAST LOS ANGELES SHOULD HAVE BEEN STUDIED

There also appears there was an intentional plan to suppress the ability for East Los Angeles residents to participate in the EIR/EIS process by splitting the community in two and placing approximately half of the community in the I-710 Corridor Project (South) and the SR 710 Project North even though the entire community is impacted by both projects. Additionally, one portion of the community is not covered by either project. In addition to being an environmental justice issue, this is a civil rights issue.

IP-37-9

By not including all of East Los Angeles, an area affected, the Draft EIR/EIS is misleading the public. The regional air quality and traffic is much worse than is being stated. There are obvious impacts to the area north of the SR 60. East Los Angeles is the only community which has the I-710 running through it that is not completely studied. It is also the only community directly impacted by two projects, the SR 710 and the I-710. Although, the current plan for the SR 710 is the TSM/TDM, it still will have impacts that should have been studied. East Los Angeles is also the only community that is split in half by each of the projects. It is one of the poorest communities with one of the largest Hispanic/Latino population in the entire I 710 Study area. This is an environmental justice issue. East Los Angeles is facing negative impacts from traffic and air pollution from both Alternative 7 and Alternative 5c. These impacts are intentionally being minimized by splitting the community in half. This has resulted in the impacts being underestimated by half.

IP-37-10

IP-37-11

IP-37-12

Leaving a great portion of East Los Angeles, an environmental justice community that is obviously affected by the project, out of the study area is a violation of CEQA and

IP-37-13

NEPA and is simply unjust. If this is allowed, it will result in a dangerous precedent. A project which results in huge increases in traffic, air pollution, cancer risks, health impacts to a community could merely be excluded from the study area to avoid having to do CEQA and NEPA analysis of impacts. This is surely not the intent of these laws. Was it not the intent of the NEPA and CEQA environmental justice laws to protect communities like East Los Angeles which is 97 percent Hispanic/Latino and has a one of the largest percentage of the population living below the poverty level than almost any other community in the study area. East Los Angeles is an environmental justice community that is being treated in a manner that is contrary to the spirit of environmental justice laws. IP-37-13

The CEQA Guidelines state that the analysis of a proposed project shall discuss "...changes induced in population distribution, population concentration, the human use of land (including commercial and residential development) ... analyze any significant environmental effects the project might cause by bringing development and people into the area affected."

The Environmental Justice Section of this report states:

All projects involving a Federal action (funding, permit, or land) must comply with Executive Order (EO) 12898, Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations, signed by President Clinton on February 11, 1994.

This EO directs Federal agencies to take the appropriate and necessary steps to identify and address disproportionately high and adverse effects of Federal projects on the health or environment of minority and low-income populations to the greatest extent practicable and permitted by law.

This Draft EIR/EIS does not take the appropriate and necessary steps to identify and address disproportionately high and adverse impacts of this project.

1) It did not complete a health impact assessment which would have identified additional impacts to the community, such as exacerbation of asthma and new cases of asthma, Reduced lung function, Cardiovascular heart disease, Preterm birth, low birth weight and pregnancy disorders, Autism, Aging of the brain, possibly obesity and Type 2 diabetes, overall burden of disease related to near roadway air pollution, increased risk of autism spectrum disorders to children born to mothers living near freeways, increased risks to the elderly. IP-37-14
2) The impacts to East Los Angeles which is clearly an environmental justice community are disproportionate and are not adequately addressed. IP-37-15
3) It did not address the disproportionate impacts to low income and minority communities in a meaningful manner. IP-37-16

The Draft EIR/EIS is deficient, replete with errors, misleading to community members, and does not properly study the impacts to East Los Angeles. Additionally, each of the deficiencies violate environmental justice standards.

This draft EIR/EIS should be thrown out and re-scoped incorporating meaningful input from East Los Angeles. Options 3A/3B should never have been included in the Draft EIR/EIS without first being presented to the I-710 East Los Angeles Local Advisory Committee. A new corrected draft EIR/EIS without East Los Angeles Options 3A and 3B should then be completed and recirculated for comment. IP-37-17

Each of the issues and problems enumerated in these comments should be addressed not only upon the issue raised but also as an environmental justice concern and as a violation of CEQA and NEPA standards. IP-37-18

A consolidating study of the environmental impacts from both projects to the entire community of East Los Angeles must be completed incorporating the latest information. A complete health impact assessment which includes all of the latest research of the impacts from living near freeways should be included. It is not like there is not significant research into the impacts of freeways on health. To ignore these studies is equivalent to the tobacco industry knowing that smoking kills and not disclosing that fact to consumers. IP-37-19 IP-37-20

EAST LOS ANGELES DESIGN OPTIONS 3A/3B:

DESIGN OPTION 3A/3B INCLUDED ON THE 2017 RECIRCULATED DRAFT OF THE EIR/EIS IS DEFICIENT BECAUSE THE IMPACTS DO NOT JUSTIFY THE BENEFITS.

We are opposed to East Los Angeles Option 3A/3B. East Los Angeles residents are opposed to East Los Angeles Design Option 3A/3B because it causes significant harm to residents and impacts community cohesion.

EAST LOS ANGELES OPTION 3A/3B CAUSES SIGNIFICANT HARM TO THE COMMUNITY OF EAST LOS ANGELES IP-37-21

THE 2017 RECIRCULATED DRAFT EIR/EIS FOR EAST LOS ANGELES OPTION 3A/3B IS DEFICIENT BECAUSE IT DOES NOT SUFFICIENTLY STUDY THE NEGATIVE IMPACTS TO THE COMMUNITY OF EAST LOS ANGELES AND CONTAINS SIGNIFICANT OMISSIONS AND ERRORS.

EAST LOS ANGELES OPTION 3A/3B IMPACTS COMMUNITY COHESION

The taking of properties on Sydney Drive and of the businesses in East Los Angeles will impact Community Cohesion.

Section 3.2.2.3 Community Character and Cohesion

East Los Angeles is a place where community cohesion is strong. The Draft EIR/EIS documents this somewhat in statistics about this community. In the community impact assessment, Section 5.13.4 it states:

> Community cohesion is the degree to which residents have a sense of belonging to their neighborhood, a high level of commitment to the community, or a strong attachment to neighbors, groups, and institutions, usually as a result of continued association over time (California Department of Transportation [Caltrans] 2011).1 According to several indicators of community cohesion for the community of East Los Angeles described in Section 4.14.6, including the long tenure of many of the residents in the study area, the high degree of ethnic homogeneity, the high percentage of persons either age 65 and over or under age 19, and the large number of residents who are pedestrians (as confirmed through the finding of high percentages of transit-dependent persons), it can be concluded that there is a high degree of community cohesion in the unincorporated community of East Los Angeles.
> This section states that CEQA requires:
>
> > Alternatively, economic or social effects of a physical change may be used to determine that the physical change is a significant effect on the environment. If the physical change causes adverse economic or social effects on people, those adverse effects may be used as the basis for determining that the physical change is significant.

IP-37-21

EAST LOS ANGELES OPTION 3A/3B CAUSES SIGNIFICANT HARM TO EAST LOS ANGELES RESIDENTS

EAST LOS ANGELES OPTION 3A/3B CAUSES PHYSICAL CHANGE TO EAST LOS ANGELES, AN ENVIRONMENTAL JUSTICE COMMUNITY:

EAST LOS ANGELES RESIDENTS ARE OPPOSED TO THE TAKING OF ANY HOMES OR BUSINESSES IN EAST LOS ANGELES

Residents feel that with the four freeways running through East Los Angeles they have met their burden. They should not have to give any more property and they should not have to endure any more pollution from these projects.

Residents of East Los Angeles will suffer both economic and social effects when their homes are acquired by Caltrans from the physical change oft adding an auxiliary lane and moving the Olympic exit to Whittier Blvd. in Option 3A/3B.

The occupants of the apartment building at 626 S Sydney Drive and of other properties that would be acquired by this project on Sydney Drive are occupied by renters. Other properties that would be required are owned by residents on Sydney.

Many families on Sydney Drive have family members who also live in East Los Angeles. East Los Angeles is an environmental justice community 97.1 percent of the population is Latino. 27.1 percent of the population have incomes below poverty level. Families with low incomes depend on extended family when money runs short. Family, and extended family is culturally important in East Los Angeles. Community members depend on their family and extended family for support. Additionally, as indicated in the East Los Angeles community profile 42.6 percent of residents are transit dependent. Marcia Carteret, M. Ed., states: IP-37-22

> "Latinos tend to be highly group-oriented. A strong emphasis is placed on family as the major source of one's identity and protection against the hardships of life. This sense of family belonging is intense and limited to family and close friends. People who are not family or close friends are often slow to be given trust. The family model is an extended one; grandparents, aunts, cousins, and even people who are not biologically related may be considered part of the immediate family.... Financial support of the family by the individual and vice versa is important and expected." http://www.dimensionsofculture.com/2011/03/cultural-values-of-latino-patients-and-families/

Expecting East Los Angeles residents to move from homes where they have extended networks of family to new homes far away from the support groups when they have no cars to visit those family members will hurt these community members both economically, socially and psychologically. Further, many of those impacted are senior citizens whose health would be impacted by one of life's great stressors... moving.

Los Angeles currently has a housing shortage. Rents are historically high throughout the Los Angeles. Community members will have difficulty finding properties to rent that are equal to and priced similarly to the rentals that they currently live at. Additionally, many renters who are given relocation money to move after one year run out of the relocation money because they are forced to pay higher rents. This has contributed to the increase in homelessness in Los Angeles. IP-37-23

As indicated in the East Los Angeles community profile, East Los Angeles has many longtime residents. The number of residents who have lived in East Los Angeles for a long period of time is greater than the County wide average. Attached are letters from residents who would be impacted if their homes on Sydney Drive are acquired through eminent domain.

Juana Cortez, age 70 lives at 600 S Sydney Drive and has lived 35 years at her home.

She states,

> "I am a senior citizen. My family who lives in East Los Angeles visit me and help me. At my age it would be hard and stressful for me to move to another location away from my family who provides for me both financially and emotionally. I also depend on my family for rides to the supermarket and doctor."

Additionally, federal law does not allow payment for relocation benefits for undocumented Immigrants. In communities like East Los Angeles with substantial numbers of Spanish speaking immigrants, it is likely that there may be undocumented immigrants who if required to move will be severely economically impacted by this project. This will cause significant harm to this population and to the overall community of East Los Angeles. IP-37-24

Additionally, the Relocation Impact Assessment is deficient in its analysis of East Los Angeles. It does not offer East Los Angeles residents the information necessary to provide comments on how this project will impact them. This is an environmental justice is as well. The Relocation Impact Report is totally flawed in its analysis of East Los Angeles. This puts East Los Angeles at a complete disadvantage. The Acquisitions Report, and Risk Maps list East Los Angeles homes as the City of Los Angeles. The map below is just one of the places within this document which misidentifies East Los Angeles as the City of Los Angeles. See map at below: IP-37-25

The Relocation Impact Report for every community facing property acquisitions except East Los Angeles, looks at housing sales, housing rentals, demographics, prices, and housing availability within that community. Caltrans appears to have included a generic Los Angeles category instead of studying East Los Angeles and providing detailed information on the availability of housing in East Los Angeles and how likely it would be

for residents to relocate within East Los Angeles. If Caltrans wanted to include the City of Los Angeles as a source of housing, they should have listed it separately, and studied East Los Angeles as an unincorporated separate community like all of the other communities were. It should be noted that none of the acquisitions of property actually occur in the City of Los Angeles. Only 14 of the 205 properties sales listings for Los Angeles are in East Los Angeles. Almost half, 102 of the sales listings are in two zip codes in South Los Angeles (90002 and 90059). (See Exhibit) Likewise, the listings for Multi-family homes are for the City of Los Angeles not one of the 55 Multifamily homes are in East Los Angeles. A good number are near downtown 90012.

IP-37-25

The Relocation Impact Study and the Community Impact Assessment incorrectly states that there are 19 homes that will be required when in fact the true number is 24. The apartment building at 626 S. Sydney Drive is a 10 unit building not a 5 unit building. This has resulted in the community of East Los Angeles not being fully analyzed for impacts and possible mitigation.

IP-37-26

This failure to adequately analyze East Los Angeles in the Relocation Impact Report means that East Los Angeles was identified as having a lack of comparable replacement housing and was not considered for further mitigation. Section 8.5 of the Relocations Sections states:

> Within the Cities of Cudahy, Vernon, and Commerce, current market conditions indicate a lack of comparable replacement housing.... While adequate comparable replacement housing appears to exist presently in neighboring cities, new replacement dwellings under Last Resort Housing may be considered for these cities as a method of providing comparable replacement housing to displaced persons who reside in areas where the replacement housing is low.

IP-37-27

The chart below is from the replacement area report.

1. **Housing stock for the study area:**

Cities	A. Number of SFR		B. Number of Multi-Family		C. Number of Mobile Homes
	For Sale	For Rent	For Sale	For Rent	For Sale
Long Beach	294	61	184	50	26
Carson	35	7	22	5	12
Compton	123	2	6	4	9
Cudahy	3	0	2	0	1
Los Angeles	205	336	55	180	0
Lynwood	32	0	1	6	1
Paramount	21	1	12	7	11
South Gate	30	2	4	1	1
Bell Gardens	5	0	3	0	0
Bell	4	0	0	2	0
Commerce	1	0	1	0	0
Maywood	3	0	1	0	0
Vernon	0	0	0	0	0
TOTAL	756	409	291	255	61

IP-37-27

The 2017 Recirculated Draft EIR/EIS is deficient in analyzing the Impacts from East Los Angeles Options 3A/3B

The impacts from East Los Angeles Options 3A/3B are not studied in the Health Risk Assessment nor in the Air Quality, Greenhouse Gas, and Health Risk Assessment Technical Study. IP-37-28

ELEVATED STRUCTURE ON BURGER:

The elevated structure that would be built adjacent to Burger Avenue will bring increased traffic to I 710 freeway through East Los Angeles as indicated below in Table 5 and 6. As capacity will increase with Options 3A/3B even more traffic will pass through East Los Angeles on the I-710. However, this has not been fully addressed in the EIR/EIS. IP-37-29

Additionally, this traffic will be closer to residents on Burger Avenue. The HRA indicates that pollution will increase more on the East side of the I-710 especially north of the I-5 and South of the SR 60. The impact that this will have on the residents who will now be closer to the freeway is not studied. The EIR/EIS is deficient. The impacts of noise from the elevated structure to residents farther from the freeway is not studied. The likely increased noise and pollution impacts are not acceptable. Options 3A and 3B should be rejected. IP-37-30

ADDITIONAL PROBLEMS WITH EAST LOS ANGELES OPTION 3A/3B

The EIR/EIS is deficient for failing to adequately review the impacts listed below:

Option 3A/3B will close the exit at Olympic moving it to Whittier Blvd.

A study analyzing the use of Olympic by trucks and vehicles has not been completed. Olympic Blvd is used by traffic going to and from Downtown Los Angeles. Many more vehicles including trucks use Olympic Bl. than use Whittier. How will moving the exit impact traffic on Eastern? Will increased traffic increase pollution in East Los Angeles?

IP-37-31

Vehicles coming off the SR 60 Pomona Freeway will be able to exit on the new Whittier Blvd. exit but traffic from the I-710 mainline will not. Therefore, vehicles searching for an exit will use the 3rd Street exit increasing traffic and cross-through traffic through a residential neighborhood.

A jogging path is due to be constructed around Calvary Cemetery which has its Eastern border on Eastern Avenue. This increased traffic will conflict with the communities use of the jogging path. The increased traffic will also increase pollution and noise. Additionally, cars speeding off the freeway frequently crash. This can make it dangerous for joggers.

IP-37-32

A signal should be placed at Eastern and Eagle to make it safer.

IP-37-33

OPTION 3A/3B will no longer allow vehicles merging from the SR 60 to access the I-5 South

IP-37-34

Vehicles coming from the SR 60 will no longer be able to exit on the 5 South. These vehicles may exit on the new Whittier exit and use East Los Angeles streets to get to the I-5 freeway. They also may stay on the SR 60 freeway and exit on Atlantic Blvd. A study of the freeway exit at Atlantic should be done to analyze this. Also, Atlantic and 3rd and Atlantic and Whittier should be analyzed. Downey Rd. may also be used by vehicles searching for another way to the I-5 freeway. This must also be analyzed. All of these possible impacts should have been studied. The increase in cross-through traffic on the streets of East Los Angeles can increase traffic on streets, increase pollution and make the community less safe.

IP-37-35

The intersection traffic assessment did not show increased traffic at Eagle and Humphreys at the 3rd St. South exit, yet Eagle, Humphreys, and Eastern are proposed for widening in anticipation of more traffic and possibly more truck traffic. When asked about the widening Engineer Shannon explained this was the reason for the increase. When asked how many more cars would exit he said 1 to 2 a minute. That is a substantial increase for a residential community. How will increased traffic impact these residential streets? Already, Eagle has experienced increased traffic when the Gold Line no longer allowed left turns from Humphreys to 3rd St. Residents on Eagle, Humphreys, and Eastern complain frequently about cars speeding off the freeway and through their neighborhoods. Accidents from cars speeding off the freeway frequently occur. Many of these go unreported because they are hit and run accidents and the residents do not have comprehensive insurance for the older vehicles that are parked on the streets.

IP-37-36

EASTERN, HUMPHREYS AND EAGLE WILL BE WIDENED.

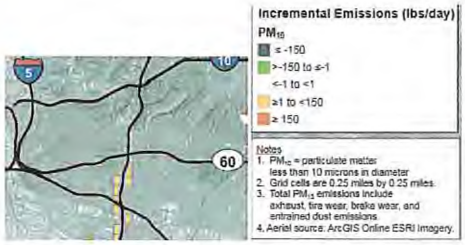
This will make it more dangerous for pedestrians. The cars speeding off the freeway will be closer to the pedestrians. They will also be closer to homes. Cars coming off the freeway

IP-37-37

have hit parked, vehicles fences, bicyclists. The last accident on Eagle St. earlier this year came within inches of hitting the fence of a home. It took out the US Mail box near the corner of Eagle and Humphreys. IP-37-37

There is not sufficient room on Eagle at the condominiums to widen the street. The sidewalk is only 5.5 feet on both sides. A resident in the condo unit uses a wheel chair. There are also other residents who live in the neighborhood who use wheel chairs. The street sidewalk needs to be fully in ADA compliance. IP-37-38

Option 3A/3B is a bad idea. IP-37-39



HEALTH RISKS:

The current 2017 Recirculated Draft EIR/EIS is deficient. It does not include all of East Los Angeles yet there are impacts from the two build projects to all of East Los Angeles see below the PM10 pollution comparisons:

Comparison of
2035 Alternative 7 to 2035 Alternative 1
Total PM_{10} Emissions

Figure 7

Comparison of
2035 Alternative 5C to 2035 Alternative 1
Total PM_{10} Emissions

Figure 6

The current Draft EIR/EIS is deficient. It does not adequately study the impacts from pollution on the residents of East Los Angeles. With this plan there are pockets of increased cancer risk, PM10 and PM2.5 pollution with the build alternatives. It is contrary to law that the environmental justice community of East Los Angeles will face increased pollution from the build alternatives. The Air Quality, Greenhouse Gas, and Health Risk Assessment Technical Study states at ES.6.1, Page 31, : IP-37-40

> Both 2035 build alternatives predominantly display decreases in cancer risk with small increases within 100 meters of the I-710 when compared to the 2035 Alternative 1 (No Build). For Alternative 7, the increase in risk is less than 1 in a million. For Alternative 5C, the maximum increase in risk is approximately 3 in a million. The primary location of increased risk for Alternative 5C is along a small portion of the I-710 just south of its intersection with SR-60; the absolute risk level at this location from I-710 traffic sources is 17.4 in a million (compared to 14.2 in a million for Alternative 1 and 14.9 in million for Alternative 7).

East Los Angeles is the only community along the corridor that shows increases in incremental cancer risk. See Figure ES8. The impacts of Alternative 7 PM10 pollution is especially troubling as is the increased cancer risk to Humphreys Avenue Elementary

School students and the residents around it from Alternative 5C. The impacts from this pollution is not adequately studied and does not contain sufficient data regarding health outcomes from the effects of PM10, PM2.5 and ultrafines. Further, the study of the impact from other pollutants is not adequately addressed. The increased cancer risk is unacceptable. IP-37-40

A Health Risk Assessment alone is not sufficient especially for a community like East Los Angeles that has 4 major freeways running through it. Additionally, East Los Angeles Option 3A/3B, impacts residents of East Los Angeles who reside within a triangle of freeways with the SR 60 to the North, the I710 to the East and the I-5 to the West. Thousands of residents within this triangle live within a few hundred feet of these freeways. Some live as close as 30 feet from the I710. This proximity requires a closer study of the impacts from the freeway on this environmental justice community. The Health Risk Assessment only addresses Cancer Risk, but Cancer Risk is not the only danger from pollution to resident's health. A Health Impact Assessment would have identified additional impacts to the community, such as exacerbation of asthma and new cases of asthma, Reduced lung function, Cardiovascular heart disease, Preterm birth, low birth weight and pregnancy disorders, Autism, Aging of the brain, possibly obesity and Type 2 diabetes, overall burden of disease related to near roadway air pollution, increased risk of autism spectrum disorders to children born to mothers living near freeways, and increased risks to the elderly. A Health Impact Assessment is needed. IP-37-41

Many studies have been completed about the impacts of air pollution on residents living near freeways. Andrea Hricko and other scientists included a listing of these studies in their comments to the SR710. This DEIR/EIS is deficient in not including these studies when reviewing the impacts. This is attached as an Exhibit.

Additionally, the impacts from pollution is not adequately studied and does not contain sufficient data regarding health outcomes from the effects of PM10, PM2.5 and ultrafines. Cancer risk is not the only danger from pollution to resident's health.

The Health Risk Assessment is flawed. The DEIR/EIS should be withdrawn, redone and recirculated.
A STUDY OF THE IMPACT OF ULTRAFINES ON EAST LOS ANGELES RESIDENTS WAS NOT INCLUDED:
Many of the homes in the East Los Angeles neighborhood near the I-710 freeway are less than a 100 feet from the freeway. Some are as close as 30 feet from the freeway. East Los Angeles Option 3A/3B would bring thousands of residents closer to the freeway, yet the impact of Ultrafines was not studied. The impact of Ultrafines to residents closer to freeways was not included. IP-37-42

In the Hricko, et al comments (Attached Exhibit), they state the following about Ultrafines:

"7. Failure to include information on the health impacts of ultrafine particles (UFPs), ...

a. Ultrafine particles (UFP; aerodynamic diameter < 0.1 micrometers) are a ubiquitous exposure in the urban environment and are elevated near highways (Fuller et al, 2012; Zhu et al, 2002a; Zhu et al 2002b; Zhu et al 2006). These particles are considered especially toxic because they can enter the lung, and stay there or get into the systemic circulation.

b. A study done by UCLA and USC researchers documented very high concentration of ultrafine particles in close proximity to the I-710 Freeway in SE Los Angeles. It found that the pollutants start to

level off at about 150 meters from the freeway and are "back to background" in about 300 meters [985 feet] from the freeway during daytime dilution conditions. See diagram below from the study (Zhu et al, 2002). In fact, the impacts for ultrafine particles are 10 to 15 times further from the source than are the daytime impacts.

c. These researchers from UCLA and USC also found that at night time when winds shifted, the pollutant levels of ultrafine particles did not reach background until 300 meters from the freeway (Zhu et al, 2006).

d. Other researchers from UCLA and USC also found that at night time when winds decrease, the concentrations of ultrafine particles did not reach background until 2500 feet from the freeway (Hu et al., 2009).

e. In fact, the impacts for ultrafine particles are 10 to 15 times further from the source than are the daytime impacts.

IP-37-42

f. The DEIR/EIS contains no estimates on what levels of UFPs one would expect to find when driving through the enclosed environment of the tunnel, nor what ambient concentrations might be expected downwind from the ventilation stacks or portals. g. Another study, by UC Davis researchers looked at a number of studies with regard to concentrations from the roadways (Karner et al, 2010). They conclude: 'In general, concentrations decay to background within a few hundred meters downwind of a road, although studies measuring pollutants solely in the evening hours indicate that higher concentrations persist beyond 500 m (1640 feet)" (citing Zhu et al, 2006). Other researchers from UCLA and USC also found that at night time when winds decrease, the concentrations of ultrafine particles did not reach background until 2500 feet from the freeway (Hu et al., 2009). See graph below from Hu et al, 2009."

Further in the Health Risk Assessment, no information is provided regarding East Los Angeles Options 3A and 3B. Options 3A/3B will remove the 24 homes of almost 100 people, included is a two-story apartment building of 10 units at 626 S. Sydney. The removal of these homes will bring the freeway closer to thousands of people living in this neighborhood. The study suggests that the sound walls will act as a barrier to pollution for residents living adjacent to the wall, but the wall on Sydney will be across the street from the remaining residences, meaning that there will be no protection from the pollution. In fact, it is anticipated that the pollution will drop onto these resident's homes. The apartment building at 626 S. Sydney because of its height acts a barrier from noise and pollution to residents across the street from it. The impacts from the increased noise and pollution without this apartment building were not analyzed.

IP-37-43

Additionally, an elevated auxiliary lane running adjacent to Burger Avenue, will bring the freeway closer to residents on the east side of the I-710 as well. The impacts to the residents are not known putting this community at a disadvantage in analyzing the impacts and understanding what the health risks are. Additionally, adding these auxiliary lanes does add capacity to the freeway which in turn increases PM10 and PM2.5 pollution from brake wear, tire wear and entrained road dust and exhaust pollution from the increased number of vehicles.

IP-37-44

Six businesses and one cell tower will be taken with East Los Angeles Option 3A/3B. One of those businesses is a Dialysis Center – Davita Doctors Dialysis Center. A google search shows only four Dialysis centers in East Los Angeles. Option 3A/3B will then remove 25 percent of the available centers. DaVita is reported to be a large Dialysis Center with 24 stations. Additionally, East Los Angeles is a Health

IP-37-45

Professional Shortage area. The population of East Los Angeles is highly transit dependent – 42.6 percent according to Table 4.14B of the East Los Angeles profile. Which means it is more difficult for residents to travel far distances for health care. Additionally, dialysis takes a lot of time making it more difficult for residents to travel far distances. Several studies have indicated that residents living near freeways who have Diabetes often have poorer health outcomes. Additionally, end stage renal failure can be a poor outcome among diabetes patients and often necessitates dialysis. Therefore, removing one of four dialysis centers will be very impactful to the community. It is ironic, living near a freeway makes diabetes worse yet Caltrans is suggesting that the treatment for that outcome be more difficult to obtain. The Draft EIR/EIS fails to study how the removal of this Dialysis Center will impact the residents of East Los Angeles. The Draft EIR/EIS is deficient. IP-37-45

The project should provide air quality monitoring to all sensitive receptors adjacent to the freeway, including but not limited to the following:

Ford elementary school (1112 S Ford Blvd)
Humphreys Avenue Elementary School (500 S Humphreys Ave)
Marianna Avenue Elementary School (4215 Gleason St)
Alphonso B. Perez Special Education Center (Michigan Ave at Ford Blvd)
Brooklyn Avenue Elementary School (4620 East Cesar E Chavez Avenue)
Hilda L. Solis Learning Academy (319 N Humphreys Ave) IP-37-46
Eastman Avenue Elementary School (4112 E Olympic Blvd)
Winter Gardens Elementary School (1277 Clela Ave)
Rowan Avenue Elementary School (600 S Rowan Ave)
KIIP Iluminar Academy (4800 East Cesar E Chavez Avenue)
Morris K. Hamasaki Elementary School (4865 E 1st St)
Belvedere Elementary School (3724 E 1st St)
Centro Estrella (4701 East Cesar E Chavez Avenue

CONSTRUCTION IMPACTS:

Sufficient information is not given to determine the extent of the construction impacts. The Recirculated Draft EIR/EIS is deficient in analyzing the impacts to residents. It is anticipated if Option 3A/3B is chosen the noise and pollution impacts to East Los Angeles residents will be considerable. During past projects, the lights and noise effected residents ability to sleep at night. The noise and pollution will substantially impact the health of residents. Many residents live less than a 30 feet from the proposed construction areas. IP-37-47

If any project is built the impacts from air pollution and noise pollution must be mitigated.

LEAD

Lead in soil will be kicked up during construction. This has not been adequately addressed in the Health Risk Assessment. Lead testing of areas where construction is IP-37-48

to occur should be tested. East Los Angeles has been contaminated with lead from Exide. The impacts of lead in the soil around construction areas to East Los Angeles residents has not been adequately studied. The extent of lead contamination in the soil to the residents north of Whittier Blvd adjacent to the I-710 is not fully known. Exide testing was limited to properties south of Whittier Blvd. CHP prior to the closure of Exide had cited trucks dripping battery acid. Because of the proximity to the Exide facilities and the I-710 there could be lead contamination on properties adjacent to the freeway. IP-37-48

It is also a concern that during construction, the Los Angeles County Fire Department's ability to enter and exit its facilities may be obstructed. It does not appear that an adequate study has been made of how to deal with this. What if a natural disaster to occur? Would the Fire Department be able exit its facilities? Seconds count in dealing with health emergencies. What is the plan to make certain that these precious seconds are not lost by construction delays? IP-37-49

TRAFFIC

The traffic analysis did not show improved Level of Service either on the I-710 nor on the streets through East Los Angeles. In fact, without the mitigation it appears that intersection Level of Service declines. Additionally, in many intersections that were not chosen for mitigation delays increased. IP-37-50

A comprehensive traffic study within East Los Angeles should be completed as indicated in the Los Angeles County Department of Public works comments and the comments of the East Los Angeles Local Advisory Committee.

The traffic study only included 4 counting stations in East LA, 3 along Whittier Blvd and 1 on Atlantic Blvd, to determine Daily Traffic Volumes. We feel that 4 segments are not acceptable to capture traffic volumes in this community, which is centered between four freeways. The project should include a comprehensive traffic study of East LA to identify the effects of spillovers, bottlenecks, and incident response on the freeway. The study should include all intersections along all main arterials including the following: IP-37-51

First Street, from Indiana Street to Vancouver Avenue
Cesar Chavez Avenue from Indiana Street to Vancouver Avenue
Eastern Avenue from Medford Avenue to Telegraph Rd
Ford Blvd from Floral Drive to Telegraph Road
Olympic Blvd from Indiana Street to Montebello Blvd
3rd Street from Indiana Street to Pomona Blvd
Whittier Blvd from Indiana Street to Garfield Ave
Atlantic Blvd from SR-60 to Telegraph Road

The current alternatives and options introduced by Caltrans provide no real traffic relief within East Los Angeles either on the freeway or on its streets. East Los Angeles streets are currently used as cross through roadways by commuters from other jurisdictions which causes pollution and congestion within East Los Angeles. During peak hours traffic spills over from the freeways to East Los Angeles streets causing traffic delays bringing pollution and misery to East Los Angeles residents. Alternatives 5c and 7 do not improve this situation in East Los Angeles. Options 3A and 3B likewise do not improve traffic within East Los Angeles. We suggest that the current Draft EIR/EIS be withdrawn and that other better alternatives and options be introduced which more fully incorporate Motion 22.1 and which study Community Alternative 7. Increasing capacity on the freeway does not reduce congestion on roadways. The adage if you build it they will come has been studied and it has been found that if you increase capacity by 10 percent driving then increases by 10 percent. See Duranton and Turner: *Duranton, Gilles, and Matthew A. Turner. 2011. "The Fundamental Law of Road Congestion: Evidence from US Cities." American Economic Review, 101(6): 2616-52.*

IP-37-52

Additionally, both truck and vehicle traffic through East Los Angeles for both Alternatives increases with the increased capacity. The Vehicle Miles Traveled through East Los Angeles increases over the no build alternatives. This increased traffic will bring more pollution and noise to the community. The anticipated Levels of Service on the I-710 through East Los Angeles show that the increased capacity merely fills up the freeway providing no benefit to East Los Angeles. This is not acceptable.

IP-37-53

Table 6. 2035 Alternative 7 Annual Average Daily Traffic Volumes
I-710 Corridor Project
Los Angeles County, California

Based on Post-Processed Traffic Data

I-710 Freeway Segment Description	AADT Volumes[2,3]					Increase in AADT Volumes[2] as Compared to 2035 Alternative 1[4]

The closure of the 3rd Street Exit South as a way of reducing cross through traffic exiting on the residential streets of East Los Angeles should be studied. IP-37-54

The following suggestions in line with Motion 22.1 to ENCOURAGE THE USE OF PUBLIC TRANSPORTATION ALONG THE I-710 CORRIDOR are proposed:

INCENTIVES TO EMPLOYERS TO REDUCE USE OF THE I-710

Offer incentives to Employers to offer free public transportation to employees who use the I-710 freeway including but not limited to free bus passes/metro passes.

Offer incentives to Employers to allow employees to arrive at work 10 minutes late and leave work 10 minutes early if they use public transportation.

Allow employers to sign up for a zip car like program for employees to use if there is a family emergency.

Offer incentives to employers of large companies to allow their employees to more easily transfer to locations near their work. (For example: Vons supermarket employees who live in East Los Angeles but work in Long Beach would be allowed to transfer closer more easily by putting in a request with the headquarters rather than with their store manager.) IP-37-55

Offer incentives to large employers who offer flexible hours allowing their employees to commute during non-peak traffic hours. The incentives could range from bragging rights such as listing them as traffic reduction champion to providing tax incentives for any costs associated with their program.

Incentives for telecommuting. IP-37-55

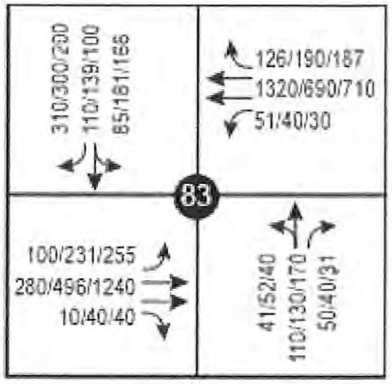
OTHER PROGRAMS:

Initiate 1st mile last mile programs all along the corridor to get public transportation commuters to their destinations.

Implement a real time Uber/Lyft like carpooling program for people to use to commute to work. In this type of program there would be no payment for the ride only for the transportation cost associated with the drive (i.e. insurance, vehicle wear and tear, gas). This way the program would not hurt taxi and UBER/Drivers. The program would do background checks for participants to ensure that sexual predators and bad drivers cannot participate. IP-37-56

Offer substantially reduced cost bus passes to people who currently use the I-710.

REDUCE POLLUTION AND FREE UP ROADWAY ALONG THE I-710



Implement an aggressive program which would identify older large vehicles driving along the I-710 freeway and offer them a program like "replace your ride" to replace the vehicles with cleaner smaller models. Smaller vehicles take up less space on the roadway and pollute less. IP-37-57

COMMENTS: MITIGATION MEASURES INTERSECTION IMPACT ANALYSIS
Intersection 83, Indiana and Olympic
According to the formula used mitigation is needed for Intersection 83. With Alternative 7, the midday peak goes from a delay of 177.6 seconds to 293 seconds. It is suggested that adding a left hand turn lane and a shared through/right-turn lane for North and Southbound approaches, traffic will improve from the 293 second delay to a 30 second delay. This improvement seems a bit optimistic. The mid day peak volumes for southbound traffic left turning traffic is 180 vehicles, for vehicles going forward or turning right it is 439.. The mid day peak volumes for Northbound left turning vehicles is much smaller only 52, whereas the right and forward bound vehicles total 170. Will having a separate left turn lane here slow traffic? This area has a lot of pedestrian traffic. IP-37-58

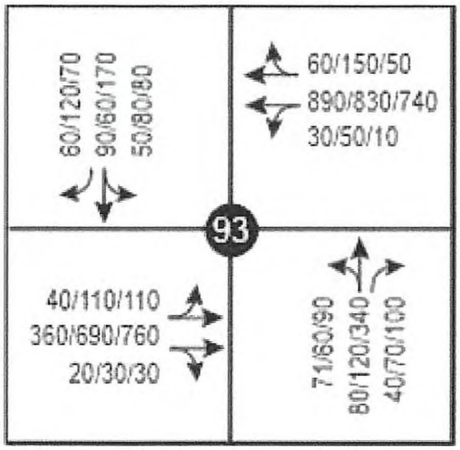
Additionally, it seems that the majority of the mid day volume is not North and South bound but East and West bound. So are the delays due to North and Southbound traffic (Total Volume 842) or from East/West Volume (1687)? IP-37-59

Finally, it appears that many of the vehicles are already going left and straight at the same time when a vehicle is making a left. Will having the left hand turn actually delay traffic? Since cars waiting to turn right when a pedestrian is crossing will block forward moving traffic which will no longer be able to go around the vehicle because they can't use the left hand lane. IP-37-60

7.2 2035 Alternative 7 Mitigation Measures

Thirty (30) study intersections have been identified to be significantly impacted under Alternative 7 considering any of the three peak-hours analyzed. All impacted intersections identified under Alternative 7 have been analyzed to determine mitigation measures to improve intersection operations and delay back to the 2035 No Build (Alternative 1) conditions, which are presented below and summarized in **Table 7-8**.

- Indiana St/ Olympic Blvd (#83): Convert both the NB and SB approaches to provide a separate left-turn lane and a shared through/right-turn lane.



Jim's Burgers #8
Tacos Super Gallito
Daniel's Test Only
E Olympic Blvd
76
Lightning Motors

INTERSECTION 93, Ford and Whittier

According to the formula used mitigation is needed.
AM Peak traffic goes from a 49.9 second delay to a 64.8 second delay.
Mid Day Peak traffic goes from a 49.4 second delay to a 65.6 second delay, and
PM Peak traffic goes from a 212.2 second delay to a 35.8 second delay.
Again the same mitigation of having a left hand turn lane and a shared forward right hand turn lane is used. Again with astounding results which improve the delays for all peak periods to under 19.5 seconds. Improving the LOS scores from DDF to BBB.

IP-37-61

- Ford Blvd/ Whittier Blvd (#93):

Convert both the NB and SB approaches to provide a separate left-turn lane and a shared through/right-turn lane.

Northbound on Ford Blvd. at Whittier.

Southbound on Ford Bl. At Whittier.

Southbound on Ford at Whittier

IP-37-61

IP-37-61

This area is a business district with a lot of pedestrian traffic. Will having a separate left turn lane here slow traffic? As can be seen in the previous photo, traffic can proceed straight when vehicles are turning right. Will having the left hand turn actually delay traffic? Since cars waiting to turn right when a pedestrian is crossing will block forward moving traffic which will no longer be able to go around the vehicle because they can't use the left hand lane.

Additionally, as seen below there is a Bus stop near the South East corner of Ford and Whittier. So when a bus is stopped here vehicles will be stopped even if the Left hand turn lane is empty. If Bus lane is moved what would be the impacts?

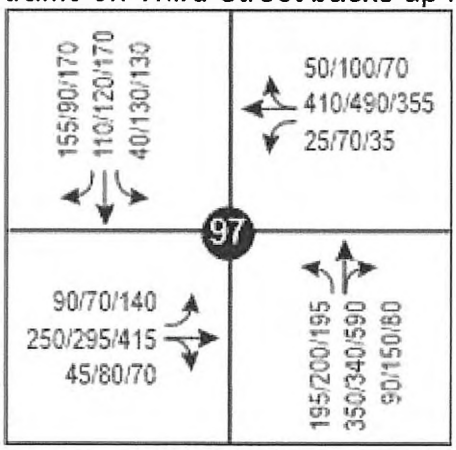
IP-37-62

As with intersection 83, the majority of the traffic is East/West bound. So it is questionable if this mitigation measure really make that much of a difference?

IP-37-63

Intersection 97, Ford and 3rd

Mitigation is required because:



Midday Peak delays increase from 44.8 to 64 seconds.

IP-37-64

This is a busy intersection with lots of pedestrians who access both buses and the Gold Line.

It does not appear there is sufficient space to add a right hand turn lane without moving the center lane over to the other side. Additionally, if a right hand turn lane was added would it actually help since 3rd Street is frequently packed with vehicles. Frequently traffic on Third Street backs up into the middle of the street.

IP-37-64

- Ford Blvd/ 3rd St (#97): Add a separate right-turn lane on the NB approach

Looking South on Ford at 3rd Street

Looking East on 3rd at Ford Blvd.

Intersection 180, 3rd and Gage

According to the formula mitigation is needed because:
The AM delay increases from 34.6 to 57 seconds. (Grade C to E)
For some reason this intersection is listed as County instead of ELA (Unincorp). It would be nice if the designation was consistent. This is a part of ELA (Unincorp). IP-37-65
See photos below: It does not appear that there is sufficient space to add a right hand turn on Gage going westbound? The acquisition of property at the South/East corner of Gage is not indicated in the Acquisitions report.

A separate righthand lane onto the Pomona SR 60 is a good idea if Caltrans Right of way is used and sufficient sidewalk space exists to accommodate ADA pedestrians. IP-37-66

SUGGESTED COMMUNITY IMPROVEMENTS/MITIGATION MEASURES
COMMUNITY BENEFIT PROGRAM

Both Build Alternatives include a Community Health and Benefit Program, which would make funding available to local jurisdictions, school districts, day care centers, community health providers, senior centers and other non-profit, to implement projects/outreach activities targeted towards improving air quality and public health within the Study Area. Given the fact that the air quality in East LA is projected would deteriorate under both project's alternatives compared to No-Built condition, the program shall also make this funding available to resident/business located within ½ mile distance from the freeway.

IP-37-67

Given that East LA is one of the few communities where project's impacts to air quality is projected would be worse than "No Built" condition, the project should include green scape projects in all schools and learning centers, and planting of additional trees and landscaping on local streets adjacent and in the vicinity of I-710 to mitigate for air quality impacts

The following are some of the mitigations and community benefits were suggested in a brainstorming session of the East Los Angeles Local Advisory Committee:

light or stop sign on 3rd St

Hot spots: Project should include a traffic study that includes all hot spots

Air filtration system must include retrofitting of the building to provide adequate results.

Project shall include solar air filter units along all sensitive receptors.

Intersection design options do not reduce traffic on or off the fwy

Project shall include lighting/Landscaping/vegetation and water conservation projects on existing on/off ramps, freeway bridges, and adjacent Caltrans properties.

22 FEET VIEW LIGHT

Monitor Air Purifier

Project shall include fencing under freeway bridges to prevent homeless encampments.

Project shall include signage with contact information on all on/off ramps and other Caltrans properties along the freeway alignment so residents may report graffiti, illegal dumping, overgrown vegetation, etc,.

Project shall include a comprehensive traffic study of the community that incorporates complete streets, first and last mile, landscaping projects, improved pedestrian lighting at uncontrolled crossings.

Solar Stop at problem intersections

Holidays Project shall include Street Banners to promote local businesses and the community

More street and intersection Studies

Lights facing opposite side of freeway

22 foot wall impacts

Project shall include Air Quality monitors at all schools within 1500 feet.

Lights facing opposite side of freeway

Add improvements within 1000 ft

Transit Oriented Development

Commercial air purifiers

Land scaping Pigeon prevention

LA County DHS to review mitigations

Soundwalls on both sides of freeway

Near Roadway Pollution

Transit Oriented Development

Community Benefit Program

Noise abatement

Xwalks - LED / Solar Synchronized Lights

Holiday lights

Trees

Long Term Contracts

IP-37-67

Air Monitors

Steam washing sidewalks

Zero parking loss

Park in ride

Parking space Count

Business mitigation / Facade improvements

Green screens

22 ft Sound walls throughout East Los Angeles

Air quality monitors to monitor the air in East Los Angeles

Air purifiers

Pigeon prevention measures on freeway walls, overpasses, along freeway

Higher quality fencing

bike racks

water recycling

complete fencing. There should not be gaps. Between sound walls. The sound walls should provide a continuous barrier from the freeway and the community.

Medical Bills subsidies

Freeway cap

ADA (Americans with Disabilities Act) Improvements

IP-37-67

Recycled water product

Cross walk on Eastern and Eagle or Eastern and 5th Street.

Stop sign on bridge on Humphreys at 3rd Street South exit

Project shall study the benefits/impacts of closing I-710 3rd St Exit South at Humphreys & Eagle

Air conditioning units for homes and businesses

Solar paneling for homes and businesses (to keep electricity costs down)

Health Impact Assessment study

Local hiring and job training

raised medians with trees and uplighting / lights

improve aesthetics and lighting of underpasses (i.e. Pico Blvd & 10 fwy)

sustainable plants

NOISE

Noise exposure: Long term exposure to moderate levels of ambient noise can increase stress, hypertension, blood pressure, heart disease, sleep

disturbance, hearing impairment, and, in children, can lead to learning delays.

Sources: Van Kempen EEMM, Kruize H, Boshuizen HC, Amelin CB, Staatsen BAM, de Hollander AEM. (2002). The association between noise exposure and blood pressure and ischemic heart disease: A meta-analysis. Environmental Health Perspective 110:307-317.
Stansfeld SA, Berglund, B, Clark C, Lopez-Barrio I, Fischer P, Öhrstrom E, Haines MM, Head J, Hygge S, Kamp I, Berry BF, and RANCH study team. Aircraft and road traffic noise and children's cognition and health: a cross-national study. The Lancet, June 4-10,2005, Vol. 365 (9475): 1942-49
Stansfeld S, Haines M, Brown B. (2000). Noise and health in the urban environment. Rev Environmental Health 15(1-2): 43-82

East Los Angeles is surrounded by four major freeways. Throughout the community noise is a problem. It disrupts sleep and makes it difficult for children to study at home. It also is a problem in East Los Angeles playgrounds. A comprehensive study on noise and the impacts it has on residents is needed for East Los Angeles. IP-37-68

If East Los Angeles Option 3A/3B is built, the SR 60 interchange running adjacent to Burger Avenue will be elevated. This can cause additional noise throughout the community. This was not adequately addressed in the DEIR/EIS.
The recommended sound walls do not eliminate the increased noise throughout the community from this project. A sound wall that is 22 feet is preferred. IP-37-69

If this project is built, mitigation is requested. The planned sound walls do not eliminate all of the increased noise impacts from the project. Additionally, some sound walls are not being built even though there are increased noise levels. All sound walls studied should be built. Sound proofing for classrooms is needed and walls should be built around playgrounds to protect children from noise. East Los Angeles residents should be offered sound proofing for their homes. IP-37-70

Because there are probable future expansion plans on the I-5 freeway and possible expansion plans on the SR60 and a planned Gold Line extension as well as the cumulative impacts from previous freeway projects through East Los Angeles all sound walls considered should be built at the maximum height to provide protection to residents from the considerable noise impacts. IP-37-71

Alternative 5C
The recommended height at the following Sound walls will not completely eliminate the increased noise for the following:

SW516 and 517: (NB Olympic to Humphreys)
The increase will be 12 d BA: **A 16 ft wall will reduce sound by 10 dBA** IP-37-72

SW 518 (Near McD, immediately South of Cemetery)
The increase will be 8 dBA A 14 ft wall will reduce the sound by 1 dBA
A 16 ft wall will reduce the sound by 2 dBA IP-37-73

No sound wall is recommended for SW 518. A sound wall should be built as a jogging track which is a sensitive use will built around the Calvary Cemetery later this year.
Note: Under 5C ELA Option, the wall will be built to protect 13 receivers. It appears this is the same location. Why the variance? IP-37-73

Alternative 5C, ELA Option
SW 516, 516A, 516B, 517 (NB Olympic to Humphreys)
The increase will be 14 dBA **A 14 ft wall will reduce the sound by 9 dBA**
A 16 ft wall will reduce the sound by 10 dBA
The 16 foot fence would provide protection to 151 homes vs 142 to for the 14 ft wall. This location is near Ford Elementary School. The taller 16 foot wall is requested, if a 22 ft wall cannot be built. Additionally, 9 more homes will be protected by the 16 foot wall. IP-37-74

SW 519 & 520 (SB Whittier to Humphreys)
The increase will be 11 dBA **A 14 ft wall will reduce the sound by 8 dBA**
A 16 ft wall will reduce the sound by 8 dBA IP-37-75
The 16 foot wall is preferred if a 22 ft wall cannot be built.

Alternative 7
SW 716 and 717
The increase will be 13 dBA **A 16 ft wall will reduce the sound by 9 dBA** IP-37-76

SW 718 (Near McD South of Cemetery)
The increase will be 8 dBA A 14 ft wall will reduce the sound by 1 dBA
A 16 ft wall will reduce the sound by 2 dBA
No sound wall is recommended for SW 718. A sound wall should be built as a jogging track which is a sensitive use will built around the Calvary Cemetery later this year.
Note: Under 5C ELA Option, the wall will be built to protect 13 receivers. It appears this is the same location. Why the variance? IP-37-77

SW 719
The increase will be 10 dBA A 14 ft wall will reduce the sound by 1 dBA
A 16 ft wall will reduce the sound by 1 dBA IP-37-78

According to the Noise Abatement Decision Report, "The Protocol establishes a process for assessing the reasonableness and feasibility of noise abatement. Before publication of the draft environmental document, a preliminary noise abatement decision is made. The preliminary noise abatement decision is based on the feasibility of evaluated abatement and the preliminary reasonableness determination. Noise abatement is considered to be acoustically feasible if it provides noise reduction of at least 5 dBA at receivers subject to noise impacts."

Caltrans' noise reduction design goal is that a barrier must be predicted to provide at least 7 dBA of noise reduction at one or more benefited receptors. It is unacceptable that Caltrans is demanding noise reductions greater than provided by the protocol. IP-37-79

For Alternative 5C - SW518 and Alternative 7 – SW718, the sound walls although meeting the protocol of 6d BA claim only one residence would benefit. Yet with the ELA Design option it is recommended as providing relief to 12 residences with 5 d BA. IP-37-80

Soundwall SW-719 should be built. It benefits the sleeping quarters of Los Angeles County Firefighters. These firefighters provide an essential service and require undisturbed sleep. IP-37-81

SOUND WALLS/ Unabated Noise:

If a project is built and it's determined that a sound wall alone is not sufficient to mitigate the noise impact to equal or below than "No Built" conditions, then a combination of sound wall and property noise abatement measures should be implemented. Special consideration should be given to the sensitive receptors adjacent to the freeway, including but not limited to the following:

Ford elementary school (1112 S Ford Blvd)
Humphreys Avenue Elementary School (500 S Humphreys Ave)
Marianna Avenue Elementary School (4215 Gleason St)
Alphonso B. Perez Special Education Center (Michigan Ave at Ford Blvd)
Brooklyn Avenue Elementary School (4620 East Cesar E Chavez Avenue)
Hilda L. Solis Learning Academy (319 N Humphreys Ave)
Eastman Avenue Elementary School (4112 E Olympic Blvd)
Winter Gardens Elementary School (1277 Clela Ave)
Rowan Avenue Elementary School (600 S Rowan Ave)
KIIP Iluminar Academy (4800 East Cesar E Chavez Avenue)
Morris K. Hamasaki Elementary School (4865 E 1st St)
Belvedere Elementary School (3724 E 1st St)
Centro Estrella (4701 East Cesar E Chavez Avenue)

IP-37-82

Proposed new sound walls in East LA will introduce patch work of mix match walls that would negatively impact the esthetics in the community. Existing sound walls should be retrofitted in-kind to match new walls. All sound walls through East LA should be of same height, color, texture and design. IP-37-83

Proposed replacement sound wall on east side of the freeway near Humphreys Avenue, should be extended more to the north to minimize noise to Humphreys Avenue Elementary School. IP-37-84

PARKING ON ATLANTIC BL. AND BUS RAPID TRANSIT

Parking on Atlantic Blvd should not be restricted during Peak hours:

The parking study does not match the experience of anyone who lives in East Los Angeles. A frequent concern of residents throughout East Los Angele is that there is not enough parking. Businesses rely on Atlantic Blvd. rely on parking in front of their businesses to provide easy access for their customers. The majority of businesses traffic is during peak pm rush hour. Limiting parking during these hours would destroy these businesses.

In talking with business owners on Atlantic during the SR 710 project North, many business owners where alarmed that parking might be restricted. Additionally, parishioners from St. Alphonsus were also alarmed as they use parking for services. Kipp Raices Charter School also depends on street parking during morning and afternoon pickup.

In evening hours during peak traffic times is when the hunt for parking on residential streets begins. Restricting parking on Atlantic would create a nightmare for residents who live adjacent to Atlantic Blvd. IP-37-85

At the East LA community meeting, it was stated that this proposal is one of several programmatic elements included in the Recirculated Draft Environmental Impact Report and that it will not be implemented by Caltrans as the Lead Agency of the I-710 Corridor Project. It would be up to local jurisdictions, in this case the County, to approve the proposed parking restrictions.

If the project was implemented the project must replace the loss of on-street parking spaces at one to one ratio, either in the form of project build parking structures or financial contribution to the local jurisdictions to pursue these.

SEE ATTACHED EMAIL COMMENTS FROM BUSINESS OWNERS:

Only zero emission buses should be used if a Bus Rapid Transit line is implemented. This is not addressed adequately in the EIR/EIS. Pollution in East Los Angeles is a problem that causes significant health problems to residents. IP-37-86

OTHER:

Possible Gold line subway Construction on Atlantic:
How this project combined with the Gold Line project would impact East Los Angeles traffic, pollution and noise is not meaningfully considered. How would this project impact the Gold Line Construction project. Would traffic numbers change? What are the cumulative impacts. What are the combined construction impacts? IP-37-87

CUMULATIVE IMPACTS

CEQA Guidelines

Section 15130(a) requires that the EIR/EIS review and analyze the cumulative impacts of a project when the project's incremental effect is "cumulatively considerable," when the new projects incremental impacts together with those of past, current and probable future projects. The focus should be on the cumulative impacts which contribute to the current project. The EIR/EIS should discuss the cumulative impacts when the projects incremental contributions are "cumulatively considerable."

Each subsequent freeway project that adds capacity adds to the noise in East Los Angeles and contributes to the misery of East Los Angeles residents in having to live with it. Cumulatively, the four freeways that run through East Los Angeles have considerable impacts. It is anticipated that a new I-5 project will be in the works shortly. Additionally, in considering the Gold Line extension along the SR 60, Caltrans commented that they did not want the Gold Line project to interfere with Caltrans ability to expand the freeway in the future. This indicates that in the future Caltrans may expand the SR60. Caltrans must mitigate to the fullest extent possible all noise and air pollution impacts in East Los Angeles, because unmitigated impacts combined with possible and probable future and past projects cumulatively combine to produce significant impacts in East Los Angeles an environmental justice community. IP-37-88

The 2017 Recirculated Draft EIR/EIS is deficient, flawed and has many errors. It should be withdrawn, redone and recirculated. East Los Angeles Option 3A/3B should not be included in the redrawn EIR/EIS. Motion 22.1 elements should be meaningfully included in the redrawn EIR/EIS. The taking of homes must be minimized to the greatest extent possible all along the corridor. Community Alternative 7 should be studied in the redrawn EIR/EIS. Input from the community of East Los Angeles should be received on any East Los Angeles options before including them in the EIR/EIS. IP-37-89

ADDITIONAL COMMENTS

NOISE/AIR QUALITY IMPACTS:

1. Noise impacts are discussed in the RDEIR/RDEIS; however, California Department of Transportation protocol does not abate noise impacts to equal or below "No Built" conditions. If it's determined that a sound wall alone is not sufficient to mitigate the noise impact to equal or below than "No Built" conditions, then a combination of sound wall and property noise abatement measures should be implemented. Special consideration should be given to the sensitive receptors adjacent to the freeway, including but not limited to the following:

   Ford elementary school (1112 S Ford Blvd)
   Humphreys Avenue Elementary School (500 S Humphreys Ave)
   Marianna Avenue Elementary School (4215 Gleason St)
   Alphonso B. Perez Special Education Center (Michigan Ave at Ford Blvd)
   Brooklyn Avenue Elementary School (4620 East Cesar E Chavez Avenue)
   Hilda L. Solis Learning Academy (319 N Humphreys Ave)
   Eastman Avenue Elementary School (4112 E Olympic Blvd)
   Winter Gardens Elementary School (1277 Clela Ave)
   Rowan Avenue Elementary School (600 S Rowan Ave)
   KIIP Iluminar Academy (4800 East Cesar E Chavez Avenue)
   Morris K. Hamasaki Elementary School (4865 E 1st St)
   Belvedere Elementary School (3724 E 1st St)
   Centro Estrella (4701 East Cesar E Chavez Avenue)

   IP-37-90

2. The project should provide air quality monitoring to all sensitive receptors adjacent to the freeway, including but not limited to the following:

   Ford elementary school (1112 S Ford Blvd)
   Humphreys Avenue Elementary School (500 S Humphreys Ave)
   Marianna Avenue Elementary School (4215 Gleason St)
   Alphonso B. Perez Special Education Center (Michigan Ave at Ford Blvd)
   Brooklyn Avenue Elementary School (4620 East Cesar E Chavez Avenue)
   Hilda L. Solis Learning Academy (319 N Humphreys Ave)
   Eastman Avenue Elementary School (4112 E Olympic Blvd)
   Winter Gardens Elementary School (1277 Clela Ave)
   Rowan Avenue Elementary School (600 S Rowan Ave)
   KIIP Iluminar Academy (4800 East Cesar E Chavez Avenue)
   Morris K. Hamasaki Elementary School (4865 E 1st St)
   Belvedere Elementary School (3724 E 1st St)
   Centro Estrella (4701 East Cesar E Chavez Avenue

   IP-37-91

3. Proposed new sound walls in East LA will introduce patch work of mix match walls that would negatively impact the esthetics in the community. Existing sound walls should be retrofitted in-kind to match new walls. All sound walls through East LA should be of same height, color, texture and design. IP-37-92

4. Proposed replacement sound wall on east side of the freeway near Humphreys Avenue, should be extended more to the north to minimize noise to Humphreys Avenue Elementary School. IP-37-93

5. Both Build Alternatives include a Community Health and Benefit Program, which would make funding available to local jurisdictions, school districts, day care centers, community health providers, senior centers and other non-profit, to implement projects/outreach activities targeted towards improving air quality and public health within the Study Area. Given the fact that the air quality in East LA is projected would deteriorate under both project's alternatives compared to No-Built condition, the program shall also make this funding available to resident/business located within ½ mile distance from the freeway. IP-37-94

6. Given that East LA is one of the few communities where project's impacts to air quality is projected would be worse than "No Built" condition, the project should include green scape projects in all schools and learning centers, and planting of additional trees and landscaping on local streets adjacent and in the vicinity of I-710 to mitigate for air quality impacts. IP-37-95

TRAFFIC IMPACTS:

7. Although both Build Alternatives, which include additional capacity improvements to the footprints of the I-710, are predicted to improve traffic conditions throughout most of the alignment, neither of these will improve the Level of Service in the mainline section between the I-5 and the SR-60. The additional lanes on the freeway will lead to longer bottlenecks of traffic between the I-5 and its terminus near Valley Boulevard, resulting on spillovers onto local arterials. While the traffic study evaluated the impacts to intersections immediately adjacent to the freeway, it did not examine the effects of spillovers and the capacity of the main arterials in the area. The traffic study only included 4 counting stations in East LA, 3 along Whittier Blvd and 1 on Atlantic Blvd, to determine Daily Traffic Volumes. We feel that 4 segments are not acceptable to capture traffic volumes in this community, which is centered between four freeways. The project should include a comprehensive traffic study of East LA to identify the effects of spillovers, bottlenecks, and incident response on the freeway. The study should include all intersections along all main arterials including the following: IP-37-96

First Street, from Indiana Street to Vancouver Avenue
Cesar Chavez Avenue from Indiana Street to Vancouver Avenue
Eastern Avenue from Medford Avenue to Telegraph Rd
Ford Blvd from Floral Drive to Telegraph Road
Olympic Blvd from Indiana Street to Montebello Blvd
3rd Street from Indiana Street to Pomona Blvd
Whittier Blvd from Indiana Street to Garfield Ave
Atlantic Blvd from SR-60 to Telegraph Road

IP-37-96

8. Both Build Alternatives include proposed peak hour parking restrictions along four arterial roadways, two of these through East LA; Atlantic Blvd between Pacific Coast Hwy and SR-60; and Cherry Ave/Garfield Ave between Pacific Coast Hwy and SR-60. While proposed parking-restrictions predict a 17% capacity improvement throughout the entire area, these restrictions will have a negative economic impact to local businesses in East Los Angeles which depend on-street parking availability for their patrons. It's our understanding that this proposal is one of several programmatic elements included in the Recirculated Draft Environmental Impact Report and that it will not be implemented by Caltrans as the Lead Agency of the I-710 Corridor Project. It would be up to local jurisdictions, in this case the County, to approve the proposed parking restrictions. The project must replace the loss of on-street parking spaces at one to one ratio, either in the form of project build parking structures or financial contribution to the local jurisdictions to pursue these.

IP-37-97

9. Both Build Alternatives include an I-710 Congestion Relief Program that would provide funding to local jurisdictions for traffic signal upgrades and coordination, safety improvements, traffic calming measures, and intersection improvements on the arterial street system in the Study Area. Given that under both Build Alternatives the capacity improvements to the footprints of the I-710 end south of the I-5, and bottlenecks are expected during peak hours on I-710 between I-5 and its terminus at Valley Boulevard, the program should also consider including Green Scape Projects to help alleviate for air quality impacts, Pavement Rehabilitation Improvement Projects to help local jurisdictions paid for maintenance of roads adjacent to the freeway and used as cut-thought when freeway gets congested.

IP-37-98

PROPERTY IMPACTS:

10. Design Options 3A and 3B aim to further improve safety and operation of the freeway by reducing weaving conflicts between the I-5 and SR-60. To achieve the objective, the variation would reconfigure the SR-60, I-5, and Olympic Blvd. interchanges, and alter the freeway and local traffic circulation in East LA. However, the Traffic Study shows this segment of the freeway will continue to

IP-37-99

operate at Level of Service F during peak hours with these design options. Residents of East LA, oppose both Design Options and the taking of 24 residential properties and 7 businesses associated with this proposal. IP-37-99

11. If property loss is inevitable, the project shall mitigate by fair market value, the taking of land in ELA, and develop comparable land within the community to maintain a "no net loss" of commercial businesses and residential housing. Project can build replacement units or provide financial contribution to the County to pursue. In addition, all relocations should take place within the limits of East LA. IP-37-100

EAST LOS ANGELES RESIDENT'S COMMENTS

Juana Cortez
600 S. Sydney Drive
East Los Angeles, CA 90022

Ronald Kosinski
Caltrans District 7, Division of Environmental Planniing
100 South Main Street, MS 16A
Los Angeles, CA 90012

Dear Ronald Kosinski,

My name is Juana Cortez . I have lived at 600 S. Sydney Drive, East Los Angeles, CA for over 35 years. I am 70 years old. I raised my family here on Sydney Drive. I have learned that my home will be taken with East Los Angeles Option 3A/3B. I am opposed to them taking my home. I am happy living here in East Los Angeles. Some of my family live in East Los Angeles. I am a senior citizen. My family who lives in East Los Angeles visit me and help me. At my age it would be hard and stressful for me to move to another location away from my family who provides for me both financially and emotionally. I also depend on my family for rides to the supermarket and doctor. IP-37-101

The relocation plan inadequate. It does not provide for how my family would be able to help me if I had to move away from East Los Angeles. There are few homes available for sale in East Los Angeles. The relocation plan only lists 14 homes in Unincorporated East Los Angeles where I live. More than half of the homes in the relocation plan are located in South Central far away from my family and friends in the Neighborhood. Also, all of the homes for sale are very expensive. We all know there is currently a housing shortage in East Los Angeles and in the nearby community. It is cruel for you to expect me at my age to leave the neighborhood where my life is. IP-37-102

I am opposed to option 3A/3B. I am opposed to the taking of any East Los Angeles homes. I am opposed to the taking of any homes on Sydney Drive. I am opposed to Option 3A/3B. I am opposed to the taking of any businesses in East Los Angeles. IP-37-103

I am opposed to increasing truck traffic on the I-710. I am concerned that Truck Traffic it will increase PM10 pollution from truck tires and brakes and will kick up more dust. Already, my house gets dusty from the pollution from the I-710. I am concerned about noise increasing because there will be more trucks and traffic. The traffic noise is already too loud especially when the trucks brake. Also, I want all of the trucks that drive on the I-710 freeway to be zero emission. There is too much pollution in East Los Angeles for residents who live less than 100 feet from the freeway like me. IP-37-104

I believe a full Health Impact Assessment should be completed for this project. The Health Risk Assessment does not fully study how this project will impact East Los Angeles residents. Noise impacts children at the local schools. I am concerned about increased cancer risk to my children at Humphreys Elementary School from Alternative 5C. IP-37-105

If a project goes forward, I want sound proofing and air filtration systems installed for homes and schools as part of a community project for East Los Angeles. The air filters for Schools must include retrofitting and filtration that is pressurized and include continuing maintenance for the systems. IP-37-106

East Los Angeles residents depend on the Kidney Dialysis Center on Eastern. It should not be removed. IP-37-107

I want cleaner air. I am concerned about pollution impacts to people who live close to the freeway like me. IP-37-108

More sound walls need to be built because there is too much noise in East Los Angeles from the freeways. The sound walls should be 22 feet. They are that tall on the west side. IP-37-109

I am opposed to losing parking on Atlantic Blvd. during rush hour. That will hurt East Los Angeles businesses. We will lose jobs and the businesses we use on Atlantic Blvd. IP-37-110

Sincerely, Juana Cortez

Juana Cortez

Dear Ronald Kosinski, Cal Trans

(✓) Me opongo a la opción 3A / 3B. Me opongo a la toma de cualquier casa del este de Los Ángeles. IP-37-111

(✓) Me opongo a que se lleven casas en Sydney Drive. IP-37-112

(✓) Si pierdo mi casa, no hay suficientes casas en East Los Angeles para que me mude en East Los Angeles.

() He vivido aquí durante ____ años. Todos mis familiares y amigos viven en East Los Angeles. Ya no podré visitar a mi familia fácilmente si tengo que mudarme. Mi red de apoyo económico está en East LA.

() Estoy envejeciendo, es posible que ya no pueda conducir en unos años. Mi red de apoyo está aquí en East Los Angeles.

() Uso el transporte público. Mi familia extendida vive en East LA. Cuento con ellos para apoyo, tanto financiero como emocional. IP-37-113

(✓) Me opongo a la Opción 3A / 3B. Me opongo a que se tomen negocios en East Los Angeles. IP-37-114

(✓) Me opongo a perder estacionamiento en Atlantic Blvd. durante la hora pico. Eso perjudicará a las empresas del Este de Los Ángeles. Perderemos trabajos y negocios que utilizamos en Atlantic Blvd. IP-37-115

(✓) Me opongo a la opción 3A / 3B. Aumentará el tráfico en Eagle y Humphreys Street y causará más accidentes. () Creo que la Third St exit South debería estar cerrada. IP-37-116

(✓) Me opongo a aumentar el tráfico de camiones en la I-710.
(✓) Me preocupa que Truck Traffic aumentará la contaminación por PM10 de los neumáticos y frenos de los camiones y levantará más polvo. Ya mi casa se vuelve polvorienta por la contaminación del I-710.
(✓) Muchas personas en mi familia tienen asma. IP-37-117

(✓) Creo que se debe completar una evaluación de impacto de salud completa para este proyecto. La Evaluación de riesgos de salud no estudia completamente cómo afectará este proyecto a los residentes de East Los Angeles. El ruido afecta a los niños en las escuelas locales. Me preocupa el aumento del riesgo de cáncer para mis hijos en la Escuela Primaria Humphreys de la Alternativa 5C. IP-37-118

(✓) Me preocupa que aumente el ruido porque habrá más camiones y más tráfico. IP-37-119

(✓) Deben construirse más muros acústicos porque hay mucho ruido en el este de Los Ángeles desde las autopistas. IP-37-120

(✓) Si un proyecto continúa, quiero instalar sistemas de filtración de aire e insonorización para hogares y escuelas como parte de un proyecto comunitario para el Este de Los Ángeles. Los filtros de aire para las escuelas deben incluir el reacondicionamiento y la filtración presurizados e incluyen el mantenimiento continuo de los sistemas. IP-37-121

(✓) Los residentes de East Los Angeles dependen del Kidney Dialysis Center en Eastern. No debería ser removido. IP-37-122

(✓) Quiero aire más limpio. Me preocupan los impactos de la contaminación en las personas que viven cerca de la autopista como yo. IP-37-123

Dear Ronald Kosinski, Caltrans

(✓) I am opposed to option 3A/3B. It will increase traffic on Eagle and Humphreys Street and cause more accidents.
(If you live on Eagle and have had your car hit by cars speeding of the freeway, let them know. If you've seen car accidents, let them know. If the traffic on Eagle makes it difficult for you let them know.)

(✓) I am opposed to option 3A/3B. I am opposed to the taking of any East Los Angeles homes.

(✓) I am opposed to the taking of any homes on Sydney Drive.

(✓) I am opposed to Option 3A/3B. I am opposed to the taking of any businesses in East Los Angeles.

( ) If I lose my home, there are not enough homes in East Los Angeles for me to relocate in East Los Angeles.
(✓) I have lived here over 16 years. All of my family and friends live in East Los Angeles. I will no longer be able to easily visit my family if I have to move.
I am getting older, I may no longer be able to drive in a few years. My support network is here in East Los Angeles.

(✓) I am opposed to increasing truck traffic on the I-710.
I am concerned that Truck Traffic it will increase PM10 pollution from truck tires and brakes and will kick up more dust. Already, my house gets dusty from the pollution from the I-710. A lot of people in my family have Asthma.

(✓) I believe a full Health Impact Assessment should be completed for this project. The Health Risk Assessment does not fully study how this project will impact East Los Angeles residents. Noise impacts children at the local schools. I am concerned about increased cancer risk to my children at Humphreys Elementary School from Alternative 5C.

IP-37-165

( ) I am concerned about noise increasing because there will be more trucks and traffic.

( ) More sound walls need to be built because there is too much noise in East Los Angeles from the freeways.

( )If a project goes forward, I want sound proofing and air filtration systems installed for homes and schools as part of a community project for East Los Angeles. The air filters for Schools must include retrofitting and filtration that is pressurized and include continuing maintenance for the systems.

(✓) East Los Angeles residents depend on the Kidney Dialysis Center on Eastern. It should not be removed.

(✓) I want cleaner air. I am concerned about pollution impacts to people who live close to the freeway like me.

NAME: Vanessa Ramirez

ADDRESS: 4431 Whittier Blvd.

EMAIL: _____

Dear Ronald Kosinski, Cal Trans

(✓) Me opongo a la opción 3A / 3B. Me opongo a la toma de cualquier casa del este de Los Ángeles.

() Me opongo a que se lleven casas en Sydney Drive.

(✓) Si pierdo mi casa, no hay suficientes casas en East Los Angeles para que me mude en East Los Angeles.

() He vivido aquí durante 25 años. Todos mis familiares y amigos viven en East Los Angeles. Ya no podré visitar a mi familia fácilmente si tengo que mudarme. Mi red de apoyo económico está en East LA.

() Estoy envejeciendo, es posible que ya no pueda conducir en unos años. Mi red de apoyo está aquí en East Los Angeles.

() Uso el transporte público. Mi familia extendida vive en East LA. Cuento con ellos para apoyo, tanto financiero como emocional.

(✓) Me opongo a la Opción 3A / 3B. Me opongo a que se tomen negocios en East Los Angeles.

(✓) Me opongo a perder estacionamiento en Atlantic Blvd. durante la hora pico. Eso perjudicará a las empresas del Este de Los Ángeles. Perderemos trabajos y negocios que utilizamos en Atlantic Blvd.

() Me opongo a la opción 3A / 3B. Aumentará el tráfico en Eagle y Humphreys Street y causará más accidentes. () Creo que la Third St exit South debería estar cerrada.

() Me opongo a aumentar el tráfico de camiones en la I-710.
() Me preocupa que Truck Traffic aumentará la contaminación por PM10 de los neumáticos y frenos de los camiones y levantará más polvo. Ya mi casa se vuelve polvorienta por la contaminación del I-710.
() Muchas personas en mi familia tienen asma.

IP-37-174

(✓) Creo que se debe completar una evaluación de impacto de salud completa para este proyecto. La Evaluación de riesgos de salud no estudia completamente cómo afectará este proyecto a los residentes de East Los Angeles. El ruido afecta a los niños en las escuelas locales. Me preocupa el aumento del riesgo de cáncer para mis hijos en la Escuela Primaria Humphreys de la Alternativa 5C.

() Me preocupa que aumente el ruido porque habrá más camiones y más tráfico.

() Deben construirse más muros acústicos porque hay mucho ruido en el este de Los Ángeles desde las autopistas.

(✓) Si un proyecto continúa, quiero instalar sistemas de filtración de aire e insonorización para hogares y escuelas como parte de un proyecto comunitario para el Este de Los Ángeles. Los filtros de aire para las escuelas deben incluir el reacondicionamiento y la filtración presurizados e incluyen el mantenimiento continuo de los sistemas.

(✓) Los residentes de East Los Angeles dependen del Kidney Dialysis Center en Eastern. No debería ser removido.

(✓) Quiero aire más limpio. Me preocupan los impactos de la contaminación en las personas que viven cerca de la autopista como yo.

() Me opongo a la opción 3A / 3B. Aumentará el tráfico en Eagle y Humphreys Street y causará más accidentes. () Creo que la Third St exit South debería estar cerrada.

() Me opongo a aumentar el tráfico de camiones en la I-710.
() Me preocupa que Truck Traffic aumentará la contaminación por PM10 de los neumáticos y frenos de los camiones y levantará más polvo. Ya mi casa se vuelve polvorienta por la contaminación del I-710.
() Muchas personas en mi familia tienen asma.

IP-37-175

(✓) Creo que se debe completar una evaluación de impacto de salud completa para este proyecto. La Evaluación de riesgos de salud no estudia completamente cómo afectará este proyecto a los residentes de East Los Angeles. El ruido afecta a los niños en las escuelas locales. Me preocupa el aumento del riesgo de cáncer para mis hijos en la Escuela Primaria Humphreys de la Alternativa 5C.

() Me preocupa que aumente el ruido porque habrá más camiones y más tráfico.

() Deben construirse más muros acústicos porque hay mucho ruido en el este de Los Ángeles desde las autopistas.

(✓) Si un proyecto continúa, quiero instalar sistemas de filtración de aire e insonorización para hogares y escuelas como parte de un proyecto comunitario para el Este de Los Ángeles. Los filtros de aire para las escuelas deben incluir el reacondicionamiento y la filtración presurizados e incluyen el mantenimiento continuo de los sistemas.

(✓) Los residentes de East Los Angeles dependen del Kidney Dialysis Center en Eastern. No debería ser removido.

(✓) Quiero aire más limpio. Me preocupan los impactos de la contaminación en las personas que viven cerca de la autopista como yo.

Comments on the SR-710 DEIR/DEIS Submitted to Caltrans by Southern California Scientists and Colleagues Who Study the Health Effects of Air Pollution and Other Public Health Impacts from Transportation Infrastructure Projects and Related Traffic*

IP-37-182

Mr. Garrett Damrath
Chief Environmental Planner
Caltrans District 7
Division of Environmental Planning
100 S. Main Street, MS-16A
Los Angeles, CA 90012

Submitted via website link
Hard copy and CD-Rom hand-delivered to District 7 Caltrans

Dear Mr. Damrath:

As we understand it, a DEIR/EIS is designed to help policymakers better understand the potential impacts of their decisions concerning infrastructure and other projects. As documented below, we do not believe the DEIR/DEIS effectively or successfully serves this purpose. Policymakers reading this version of the DEIR/EIS will have a very difficult time understanding what the air pollution impacts of a proposed SR-710 extension would be, particularly as it pertains to the tunnel alternative.

We respectfully submit our concerns as a group of scientists and public health experts. Some of us have been studying the health effects of air pollution in southern California individually and collectively for decades. Others are experts in public health, working to ensure that the community is adequately informed of the potential health impacts of new infrastructure projects, and that proposed infrastructure projects are designed to minimize environmental and health impacts.

Southern California has a world-class community of scientists and experts studying the health impacts of air pollution and other impacts from infrastructure projects that is unique in this field. Despite there being hundreds upon hundreds of published papers on this topic by investigators from the University of Southern California (USC), University of California, Los Angeles and Irvine (UCLA and UCI), and other investigators around the world, the DEIR is completely lacking in a discussion of the health effects of air pollution related to the alternatives, other than diffuse claims that the project will "improve air quality."

corridor, yet the words "goods movement" or "freight" do not appear in the purpose and need statement.

b. Metro officials have previously stated that this, indeed, is why completing the 710 north gap closure is so valuable. Please see this 2011 statement by Douglas Failing, then executive director of highway programs for Metro: *"The 710 north gap closure between the I-10 and the I-210 would complete the natural goods corridor that was begun several decades ago."* Please find this quotation at: http://www.metro.net/news/simple_pr/metro s-highway-program-shifts-high-gear-18-new-pro/

c. Thus, the Purpose and Need of the Project, as stated, is erroneous because it fails to mention that a major purpose of the SR-710 tunnel project is to complete the "goods movement corridor" which heads north from the Ports of Los Angeles and Long Beach, between the I-10 and the I-210 Freeways. For this reason alone, the DEIR/EIS merits revision and recirculation for comments and additional opportunity for review.

3. **Failure for the DEIR/EIS to accurately inform the public and policy decision-makers about the volume and impact of heavy duty diesel big rig trucks in the tunnel – and along the lengthy approach to the tunnel's portals.**

a. The DEIR/DEIS's truck traffic estimates greatly minimize freight traffic, instead relying on a set of "FAQs" about goods movement which have no citations, admit that detailed truck studies were not performed, and are completely misleading to the public. An example is the following statement from the FAQs: *"Construction of a tunnel would not be expected to alter truck traffic destinations. Cars and trucks that are already going north (via surface streets or other freeways) may choose to take a tunnel to reduce their travel time, but no additional truck traffic will go north."* See http://media.metro.net/projects_studies/sr_710/images/sr_710_faqs_goods_movement.pdf. The public and policy makers deserve an accurate and appropriate method for estimating truck traffic in the Tunnel Alternatives – from the Ports and elsewhere – and the DEIR/DEIS should provide one. It currently does not. We request that Caltrans and Metro permanently remove this misleading set of "Frequently Asked Questions" from its web portals and websites.

b. On page 5-35 of the Air Quality Assessment, the DEIR/DEIS states *that "there is a possibility that some traffic currently utilizing other routes would be attracted to use the new facility."* This ignores the widely accepted concept of "induced demand," in which increases in traffic capacity are quickly met with increased traffic volumes whenever a new freeway is built or new lanes added. Certainly Caltrans is aware of the concept of "induced demand" when a new freeway is built. In a 2014 draft policy brief for the California Air Resources Board, two experts concluded that there is usually a growth in both vehicle miles traveled (that is there is "induced demand," as more people choose to use the new highway) and in greenhouse gas emissions after a "capacity expansion" of a highway. They argue that the "induced demand" generally offsets any reductions in greenhouse gas (GHG) emissions that would result from improved traffic flow (Handy and Boarnet, 2014. *"Given the induced travel effect, capacity expansion has limited potential as a strategy for reducing congestion*," Handy and Boarnet conclude. (See

http://www.arb.ca.gov/cc/sb375/policies/hwycapacity/highway_capacity_brief-4-21-14.pdf.

c. Truck estimates vary widely throughout the document, and these assumptions are critical to the Health Risk Assessment, the Air Quality Assessment, and other issues in the DEIR/EIS.
   i. We note that the SR-710 tunnel project would allow, for the first time, trucks to travel north from the Ports for a continuous 30 miles on the I-710 to SR-710 Freeway directly to the I-210 (and then on north to the Central Valley or east to distribution centers in Riverside and San Bernardino Counties, or other points East). But Table 5.6 on increased VMT that will occur with tunnel project in the Air Quality Assessment makes little sense. It seems to show that at the I-210 eastbound on-ramp, there would be only about 400 more vehicles a day on the on-ramp if the tunnel allowed trucks than if it did not.
   ii. Inexplicably, Table 3.5.7 on Truck Performance (see below) shows nearly identical "Vehicle Miles Traveled (VMT) for trucks in the No Build, Light Rail, and Tunnel Alternatives. How can the same VMT for trucks traveling in the "No Trucks Allowed Tunnels" occur as in tunnels that allow trucks? It is imperative to have a valid estimation of trucks in the tunnel if one is to have a valid Health Risk Assessment.

Table 1. 2035 Truck VMT with various alternatives, from the DEIR/EIS

TABLE 3.5.7:
Opening Year (2020/2025) and Horizon Year (2035) Truck Performance by Alternative

Performance Measure	No Build	TSM/TDM	BRT	LRT	Freeway Tunnel Alternative					
					Single-Bore Design Variation			Dual-Bore Design Variation		
					Toll	Toll, No Trucks	Toll, Express Bus	No Toll	No Toll, No Trucks	Toll
Opening Year 2020 (for the TSM/TDM and BRT Alternatives)										
Daily Truck VMT per Lane Mile of Freeway	2,300	2,300	2,300	N/A	N/A	N/A	N/A	N/A	N/A	N/A
Daily Truck VMT per Lane Mile of Arterials and Collectors	100	100	100	N/A	N/A	N/A	N/A	N/A	N/A	N/A
Opening Year 2025 (for the LRT and Freeway Tunnel Alternatives)										
Daily Truck VMT per Lane Mile of Freeway	2,500	N/A	N/A	2,500	2,500	2,400	2,500	2,500	2,400	2,400
Daily Truck VMT per Lane Mile of Arterials and Collectors	105	N/A	N/A	105	95	105	95	95	100	95
Horizon Year 2035 (for all Build Alternatives)										
Daily Truck VMT per Lane Mile of Freeway	2,800	2,800	2,800	2,800	2,800	2,700	2,800	2,700	2,600	2,700
Daily Truck VMT per Lane Mile of Arterials and Collectors	115	115	115	115	105	115	105	95	105	105

Source: *Transportation Technical Report* (2014).
Note: The truck-related information provided in this table refers to heavy-duty trucks as defined in the Southern California Association of Governments 2012 Regional Transportation Plan travel demand model.
N/A = Not Applicable
VMT = vehicle miles traveled

   iii. In contrast to the above, which estimates a minimal amount of trucks expected with the Tunnel Alternative, Table 4-12 shows that in 2035 there would be 25,600 trucks a day in the tunnel.

Table 2. 2035 modeled truck counts along the I-710 and in the tunnel from the DEIR/EIS

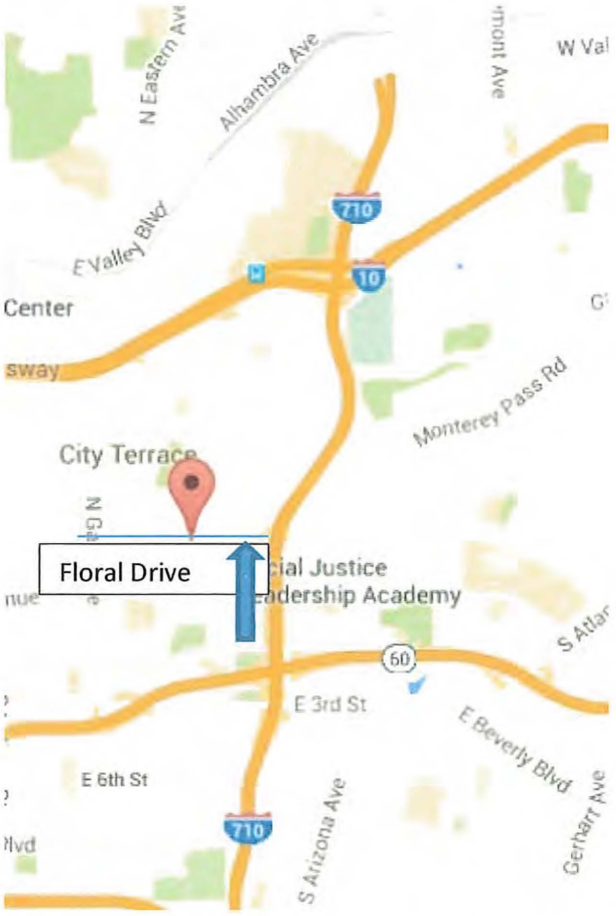

TABLE 4-12
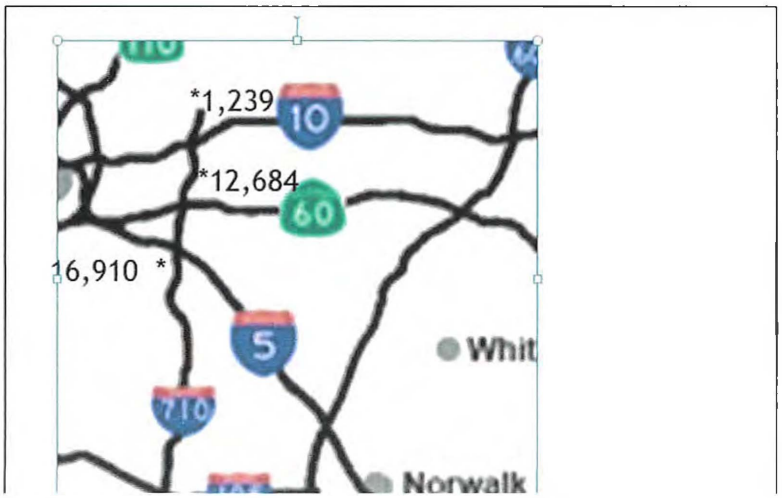
Travel Model Comparison Summary: SR 710 North and I-710 South
SR 710 North Study, Los Angeles County, California

Location	SR 710 North Model (2035) [1]			I-710 South Model (2035) [1]			Comparison	
	Daily			Daily			Daily	
	Total	Trucks	% Trucks	Total	Trucks	% Trucks	% Diff	% Truck Diff
SR 710 Tunnel	177,600	25,600	14.4%	166,200	18,600	14.7%	-6%	-27%
I-710 North of Floral Drive	220,000	26,500	12.0%	226,900	20,300	14.7%	3%	-23%
I-710 North of Whittier Boulevard	265,800	37,000	13.9%	256,400	27,300	14.7%	-4%	-26%
I-710 North of Washington Boulevard	315,700	31,400	9.9%	274,700	30,200	14.7%	-13%	4%
I-710 South of Imperial Highway	272,100	37,500	13.8%	249,900	36,700	14.7%	-8%	-2%

[1] The model results shown for 2035 for both SR 710 North and I-710 South include the SR 710 North tunnel and the I-710 South truck lanes. Both models assumed the SR 710 tunnel was designed as the dual-bore tunnel without a toll variation.



The above table also shows that on the I-710 north of Floral Drive there would be 26,500 trucks anticipated in 2035. Floral Drive is between the SR-60 and the I-10 Freeway. This is a clear indication that East Los Angeles will be seriously impacted by truck traffic when the tunnel opens. See map below for where Floral Drive is.

Map 1. Red mark and blue line showing east-west location of Floral Drive in East L.A. This can be matched with truck counts in Caltrans table above.

iv. The current volume of trucks that travel north of the SR-60 and north of the I-10 on the I-710 Freeway were obtained from Caltrans online truck counts and are shown below:

Map 2. Truck Counts Caltrans Data, 2013 in the study area

The above truck counts show that in 2013 there were 16,910 trucks (one way) on the I-710 north of the 5 Freeway. Some 4000 trucks exited on the SR-60. Another 11,000 trucks exited on the I-10, meaning that only 1,239 trucks were left on the I-710 when it ended in Alhambra. These data are from the following Caltrans table of truck counts:

Table 3. Caltrans truck counts along the I-710 during 2013

v. When using data from the Table 4-12 in the DEIR/EIS, the following maps show how many trucks are on the I-710 today in the study area versus how many are predicted through modeling for the future, when the tunnel is open.

Map 3. Comparison of truck counts in 2013 along the I-710 Freeway and 2035 predictions if the tunnel alternative is selected.

2013 truck counts

2035 truck predictions

vi.

4. **Failure to describe or discuss studies and rulings that conclude that diesel exhaust and diesel particulate are carcinogens, which is critical to understanding the potential health risks of a tunnel alternative.**
   a. We note that once constructed both the single bore tunnel and the dual bore tunnel would have "diesel PM emissions greater than or equal to the 2025 and 2035 emissions" (see page 35 of Executive Summary/DEIR/EIS).
   b. Despite the above, concerns about the health impacts of diesel exhaust and diesel PM are minimized in the DEIR/DEIS. We can locate no mention of the 1998 ruling by the California Air Resources Board naming diesel particulate as a Toxic Air Contaminant because it causes cancer, nor of the 2012 ruling by the World Health Organization's International Agency for Research on Cancer (IARC) designating "diesel exhaust as a Class I carcinogen."
   c. Page 2-17 of the HRA includes a lengthy description of OEHHA's risk assessment uncertainties in 2002, but does not include anything about OEHHA's diesel cancer risk assessment in 1998 (http://www.arb.ca.gov/toxics/dieseltac/part_b.pdf) which summarized more than 40 studies published before 1998 showing the diesel particulate causes cancer. The HRA also does not describe the new OEHHA Diesel Cancer Risk Guidelines

(proposed in 2014 and finalized in 2015). See 2014 proposal, issued before the DEIR was released and 2015 final guidance:
http://oehha.ca.gov/air/hot_spots/riskguidancedraft2014.html
http://oehha.ca.gov/air/hot_spots/hotspots2015.html.
To our knowledge, the DEIR/EIS has no discussion of the multitude of studies showing that diesel causes cancer and other health effects, summarized in the the OEHHA document cited above or more recent studies, examples of which are in the References (Zhu et al, 2002; Olsson et al, 2011; Silverman et al, 2012; Attfield et al, 2012; Bhatia et al, 2012; Silverman et al, 2014; Vermeulen et al, 2014).

d. Pages 5-25 and 5-26 of the Air Quality Assessment fail to mention action in California in 1998 that declared diesel as a Toxic Air Contaminant, with a unit risk value of cancer potency for cancer risk. But it has several pages about concerns and uncertainties expressed at the national level about diesel, from the Health Effects Institute and U.S. EPA, in an apparent attempt to downplay the health effects of diesel exhaust. For example: page 3.13-34 of the DEIR/EIS states that: "*... there is no national consensus on air dose-response values assumed to protect the public health and welfare for MSAT compounds, and in particular for diesel PM. The EPA and the Health Effects Institute have not established a basis for quantitative risk assessment of diesel PM in ambient* settings. *There is also the lack of a national consensus on an acceptable level of risk."* However, California's OEHHA and the regions South Coast AQMD have, respectively, adopted quantitative risk value and an acceptable level of risk, which the DEIR/EIS fails to acknowledge.

5. **Failure to use the most recent guidance from OEHHA in development of the Health Risk assessment for determining cancer risk from exposure to diesel exhaust; the HRA must be redone.**
   a. Although OEHHA had issued a draft of its new guidance document prior to completion of the DEIR/EIS, the Health Risk Assessment fails to include calculations for how this new guidance (now adopted) would impact the HRA. http://oehha.ca.gov/air/hot_spots/riskguidancedraft2014.html. The HRA should redone using the latest guidance document at: http://oehha.ca.gov/air/hot_spots/hotspots2015.html.

6. **The Health Risk Assessment (HRA) has many other flaws including inadequate information about the most impacted individuals.**
   a. It fails to provide all necessary background assumptions about traffic volumes and minimizes the air pollution in both the approach (above SR-60 to the I-10) to and the exit from the South Portal (impacting East L.A. and Alhambra residents). In addition, the HRA does not provide a map showing the most impacted individuals/workers/students (see Table 3-4). An informative map must be included. The HRA must be redone to address traffic approaching the South Portal, to better address the cancer risk which is currently claimed to be "zero" due to the ventilation towers (see page ES-3) which states "Due to the installation of the particulate matter control system at the tunnel ventilation system, vehicle emissions from the tunnel ventilation towers contribute minimally to the cancer risks at the MEIR and MEIW locations" (that is most impacted

resident and most impacted worker). Please provide page numbers for these calculations.

b. The Health Risk Assesment states that "the maximum student cancer risk is at Maranatha H.S. west of the SR-710 near the north portal." Did Caltrans alert this school to the increased noise and cancer risk that this project would bring to the school and its students and teachers?

c. Page 3-8 of the HRA states that "the area with cancer risk greater than 10 in one million is a narrow strip around the north and south portals and the adjacent interchange. There appears to be no analyses performed for increased cancer risks between the SR-60 and the portal of the tunnel even though there would be thousands more vehicles on the freeway when the tunnel opens. This increase in traffic on the I-710 due to the tunnel opening is completely ignored in the DEIR/EIS and its analyses for cancer risk – and for noise (see below). This is a major flaw in the HRA and the DEIR/EIS.

7. **Failure to include information on the health impacts of ultrafine particles (UFPs), the levels of exposure to passengers traveling in the tunnel, whether the UFPs would be "captured" by the particulate filters that are planned in the ventilation stacks, and how far from the portals and approach roads the ultrafine particles would travel.**

   a. Ultrafine particles (UFP; aerodynamic diameter < 0.1 micrometers) are a ubiquitous exposure in the urban environment and are elevated near highways (Fuller et al, 2012; Zhu et al, 2002a; Zhu et al 2002b; Zhu et al 2006). These particles are considered especially toxic because they can enter the lung, and stay there or get into the systemic circulation.

   b. A study done by UCLA and USC researchers documented very high concentration of ultrafine particles in close proximity to the I-710 Freeway in SE Los Angeles. It found that the pollutants start to level off at about 150 meters from the freeway and are "back to background" in about 300 meters [985 feet] from the freeway during daytime dilution conditions. See diagram below from the study *(Zhu et al, 2002)*. In fact, the impacts for ultrafine particles are 10 to 15 times further from the source than are the daytime impacts.

Figure 1. Ultrafine particle size distributions near the I-710 Freeway

Fig. 4. Ultrafine particle size distribution at different sampling locations near the 710 freeway.

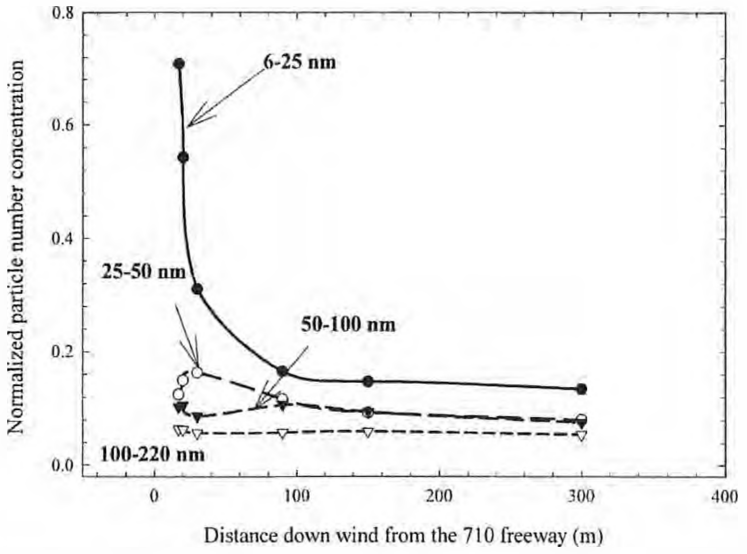

Fig. 5. Normalized particle number concentration for different size ranges as a function of distance from the 710 freeway.

c. These researchers from UCLA and USC also found that at night time when winds shifted, the pollutant levels of ultrafine particles did not reach background until 300 meters from the freeway (Zhu et al, 2006).
d. Other researchers from UCLA and USC also found that at night time when winds decrease, the concentrations of ultrafine particles did not reach background until 2500 feet from the freeway (Hu et al., 2009).
e. In fact, the impacts for ultrafine particles are 10 to 15 times further from the source than are the daytime impacts.
f. The DEIR/EIS contains no estimates on what levels of UFPs one would expect to find when driving through the enclosed environment of the tunnel, nor what ambient concentrations might be expected downwind from the ventilation stacks or portals.
g. Another study, by UC Davis researchers looked at a number of studies with regard to concentrations from the roadways (Karner et al, 2010). They conclude: *'In general, concentrations decay to background within a few hundred meters downwind of a road, although studies measuring pollutants solely in the evening hours indicate that higher concentrations persist beyond 500 m (1640 feet)"* (citing Zhu et al, 2006). Other researchers from UCLA and USC also found that at night time when winds decrease, the concentrations of ultrafine particles did not reach background until 2500 feet from the freeway (Hu et al., 2009). See graph below from Hu et al, 2009.

Figure 2. Ultrafine particles, distance from freeway

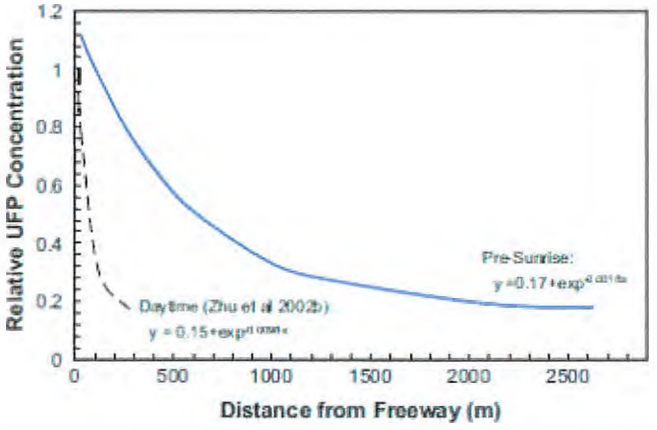

Fig. 6. Exponential fits to the downwind relative UFP concentrations with distance from the I-10 freeway during pre-sunrise hours, compared with fit to daytime data downwind of the I-405 freeway by Zhu et al. (2002b). Data were acquired continuously for pre-sunrise measurements, up to the edges of the freeway.

Also see table below from the UC Davis study which shows that many pollutants do not reach background level until 1000 meters or more (Karner et al, 2010).

Table 4. UC Davis Study summary

TABLE 1. Summary of Background Normalized Data

group	pollutant	approximate multiplier above background concentration at edge-of-road	approximate distance required to reach background concentration (m)[a]
rapid: >50% drop by 150 m	CO	21[b]	—[c]
	metal deposition	2.9	161
	UF1 particle no.	4.0	189
less rapid or gradual decay/change	benzene	2.1	280
	EC	1.7	420[d]
	NO	3.3	565[e]
	NO_2	2.9	380[f]
	NO_x	1.8	570[e]
	PM_{10}	1.3	176
	UF2 particle no.	4.8	910[e]
	VOC1	2.0	270

[a] The approximate distances were derived from an expanded version of Figure 2; the distance point at which the smoothed line reached a value of one on the *y*-axis is cited here as background. [b] Near-road CO concentrations extended outside of the range plotted in Figure 2. [c] CO concentrations did not reach background within the 285 m for which data were measured. [d] Background normalized concentrations attained an approximate minimum value of 1.1 at this distance from the road. [e] Reached background concentrations outside of the range plotted in Figure 2. [f] Background normalized concentrations attained an approximate minimum value of 1.08 at this distance from the road.

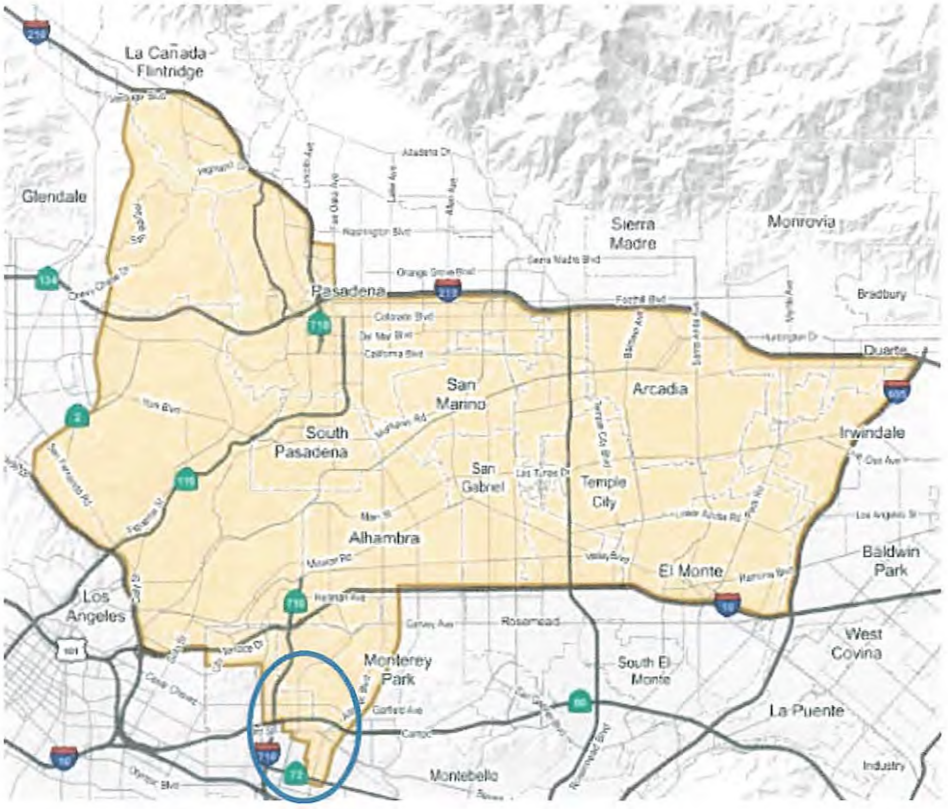
The authors concluded that *"background normalized results suggest that a range of approximately 160-400 meters [525-1312 feet] is sufficient to reach background concentrations for the majority of pollutants."*

Dozens of studies on ultrafine particles by investigators at the UCLA Particle Center directed by John Froines and by Costas Sioutas and his laboratory at USC are not included in any references or discussion in the DEIR/EIS. In fact, there are no

references to any studies on ultrafine particles, which is of great importance to the building of a tunnel alternative for the SR-710. (Examples: Delfino et al, 2005; Fanning et al, 2007; Kleinman et al, 2009; Fuller et al, 2012; Zhu et al, 2002; Zhu et al 2006)

8. **The Air Quality Assessment (the AQA) has multiple flaws and does not provide adequate information to either the public or policymakers who must select an alternative.**
    a. The AQA mentions "sensitive receptors" but fails to include a map of where all of the sensitive receptors are. Such a map must be included in a revised DEIR/DEIS. The public and policymakers cannot be expected to "imagine" where the most sensitive receptors are based on seven pages of coordinates rather than visually presenting them on a map in the DEIR/EIS.
    b. The Air Quality Assessment fails to describe operating filtration specifications of the ventilation system that will be installed in the tunnel and in the two ventilation stacks, making it nearly impossible to determine the accuracy of the claim that the stacks will remove 80% plus of the particles and gases.
    c. Air quality levels are shown in Table 3.13.1 at the South Wilson Pasadena station, but fail to show PM2.5 levels for 2013, without an explanation. Failing to include the most recent levels for a significant pollutant is not acceptable. Similar problem with Tables 4-1 and 4-2 of the air quality analysis which fail to show PM10 levels for multiple years at the Pasadena station.
    d. The assessment sometimes refers to tunnel mitigation measures as "scrubbers" and other times as "filtration devices." There is no discussion of best practices in ventilating tunnels throughout the world. Thus neither the public nor policymakers can evaluate the efficacy of the mitigation measures suggested in the context of experiences elsewhere.
    e. If a tunnel alternative is selected, there needs to be a better evaluation of what the contaminant levels and potential health risks inside the tunnel would be for those using the 4-mile tunnel. This needs to include truck estimates, based on validated truck studies (which have not been conducted according to the FAQs). A recent study (Orru et al, 2015.) estimated that there could be increased mortality due to tunnel exposures for those frequently using a proposed high volume urban tunnel in Stockholm.
    f. If a tunnel alternative is selected, there needs to be more information about the emissions and air dispersion from both portals of the tunnel and from the tunnel's ventilation stacks. The stacks are designed to primarily remove particles, not gases. Several experts have evaluated the tunnel ventilation and have submitted a separate set of comments on that topic.
    g. We request that Caltrans/Metro describe and detail the maintenance plans for how they will maintain the filtration devices as part of the tunnel air pollution control plan. This cannot be found in the DEIR/EIS.
    h. More information is needed to advise the public about details of an "exhaust duct along the entire length of the tunnel and jet fans within the tunnel." We can find no details about this technology.

9. **Failure to estimate what the pollution levels will be at the North and South Portals.**
    a. These portals are near schools and an acute care hospital and the air that rushes out from traffic will not be filtered at either portal. A voluminous medical literature has demonstrated the acute effects of particulate pollution on heart attacks, yet

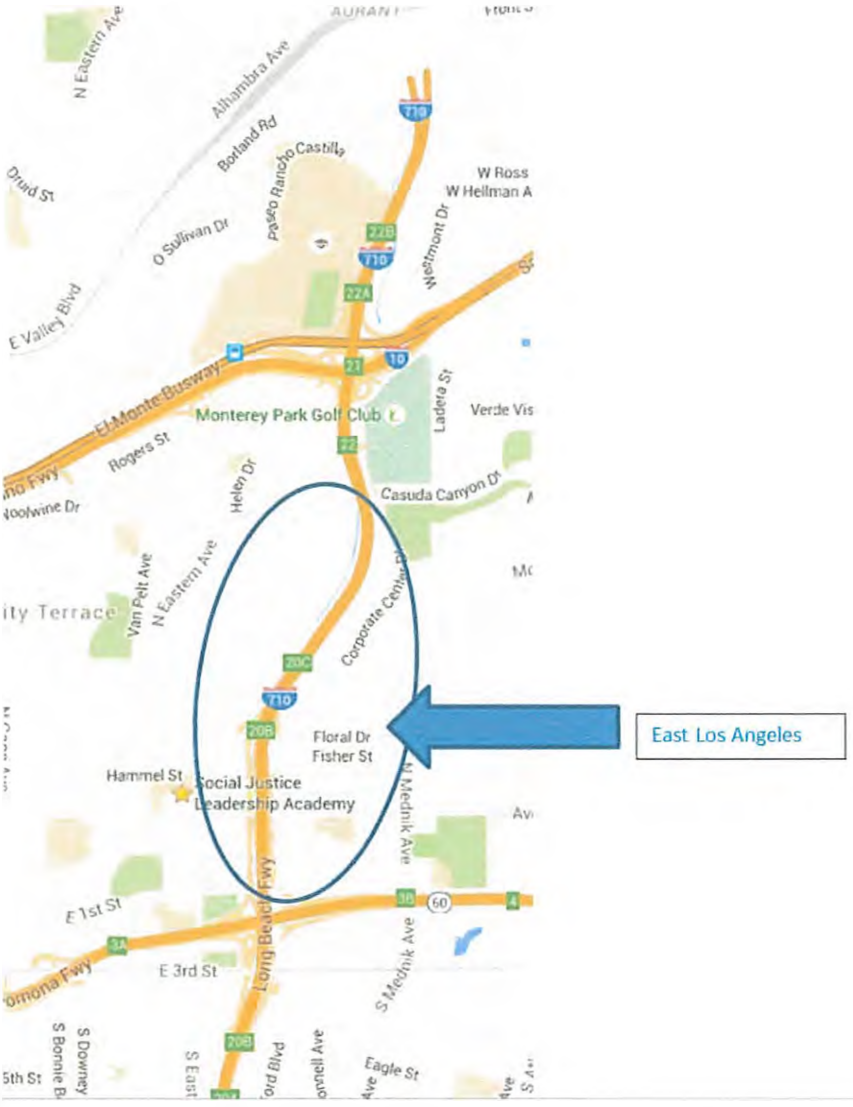


there is no consideration of the potential impact on patients with heart attacks at Huntington Hospital at high risk of lethal post-infarct arrhythmias.

i. We request that if we are incorrect and the DEIR/EIS includes information about these effects, that the pages on this be made public and sent to u as commenters.

10. **The DEIR/DEIS includes a faulty "study area" that fails to include impacted parts of unincorporated East Los Angeles, making this an environmental justice issue.**

a. The study area is described as "approximately 100 square miles and generally bounded by I-210 on the north, I-605 on the east, I-10 on the south, and I-5 and SR 2 on the west." (See front page of DEIR/DEIR). That means that the area between the SR-60 and the I-10 adjacent to the I-710 has not been studied with regard to the Freeway Tunnel Alternatives, thus failing to recognize the immense impact on East L.A. that vehicle traffic will create as drivers travel in or out of the South Portal. (See map below). The map below shows the study area – but the part of East L.A. that is shown is only studied with regard to the LRT alternative, not for the tunnel alternative



Map 4. DEIR/EIS Study Area. *Area circled was studied in the DEIR/EIS for the Light Rail Alternative but apparently not for the tunnel alternatives.*

b. In addition, the I-710 South DEIR/EIS evaluates impacts only from the south I-710 north to the SR-60, meaning that the East L.A. stretch of the I-710 is not evaluated in *either* DEIR/DEIS. East L.A. is 97% Hispanic, and there are multiple

sensitive receptors in this area. Failure to discuss the impacts of increased emissions and traffic in East LA make this is an environmental justice issue.

Map 5. The SR-710 DEIR/EIS "study area" exclusion zone. East L.A. was studied only for the Light Rail Alternative. It was not studied for volumes of additional truck or other vehicle traffic nor for noise mitigation nor for cancer risk.

c. Table 3-1 claims that there will be a "negative" cancer risk (that is reduced) as a result of building the tunnel alternative.
d. Also Table 3-4 calculates the "incremental cancer risks" for various alternatives. For some unexplained reason no addresses near the South Portal are included (See page 3-6 of HRA). We note that the text of the HRA states that "localized

cancer risk increases occur mostly near the tunnel portal areas and extend to the nearby interchanges and highways that vehicles would use as the main routes to or from the new freeway tunnel."... "In the south, cancer risks would increase near the south portal and extend south to the SR 710/I-10 interchange."

e. In fact, the cancer risks will not stop at the SR 710/1-10 interchange; they must be evaluated for the area within the area above, extending down to the SR-60. There will be thousands more trucks traversing the I-710 between the SR-60 and the SR-710 and these impacts of adjacent communities are not considered in SR-710 DEIR/EIS
    i. If the 25,000 pages of the DEIR/EIS include information about elevated cancer risk from more traffic and more trucks on the I-710 north of SR-60, please provide the page numbers where this information appears.
    ii. Again, this area of East L.A. is not considered in the DEIR/EIS and HRA – as though it does not exist and will not be impacted. This is a serious flaw and an environmental justice issue in the DEIR/EIS and HRA. (See page 3-8 of HRA).
f. Despite claims to the contrary in the DEIR/DEIS, if a tunnel alternative is selected, there will be significantly more traffic on the existing stretch of the I-710 Freeway heading north between the SR-60 and the I-10.
    i. The DEIR/DEIS must perform an evaluation of the air pollution impacts on homes and schools on this stretch of the I-710. Currently, homes and schools in East L.A. are evaluated only for the light rail alternative. There is no analysis of noise or air pollution impacts in this area, although it will be heavily affected by truck traffic from the Ports of Los Angeles and Long Beach traveling to or from the new tunnel. This is an environmental justice issue.

11. **The DEIR identifies high risk receptors near the north portal but not near the south portal.** In Table 3-4 of the HRA, a number of higher risk receptors are identified. Although there are higher risk receptors identified near the NORTH portal, there are none identified near the SOUTH portal. In addition, there is no map showing the areas with highest risk at the South Portal. Although page 3-8 of the HRA states that cancer risks would increase near the South Portal, there is no table showing the locations where that would occur. There need to be maps of the high risk receptors at both portals.

12. **The DEIR fails to look at zero emissions technology either for trucks going through the tunnel or for its Bus Rapid Transit (BRT) alternative.** Although Metro is the lead agency in the region of a collaborative on use of zero emissions technologies for transportation (see http://www.metro.net/projects/countywide-zero-emission-trucks-collaborative/), there is no discussion of requiring that trucks using the tunnel be zero emission technology nor of having truck age restrictions so that only newer trucks could use the tunnel. Although Metro has just bought five battery-electric buses for its fleet, there is no mention of using this zero emission technology for the BRT alternative, which is listed as an alternative to the tunnel.

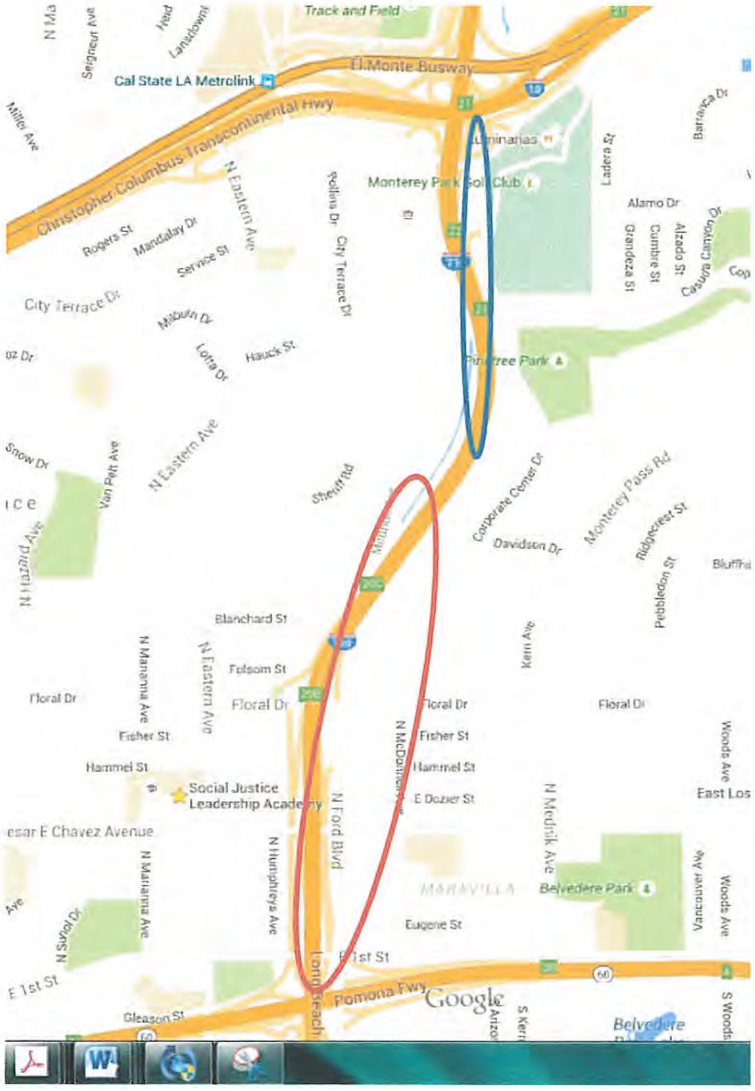
13. **Concerns about increase noise levels from traffic entering and exiting the tunnel and increased traffic volumes along the approaches to the tunnel are minimized in the DEIR/EIS without scientifically sound analyses or even tables showing the noise measurements and analyses.**

a. The Project will generate two distinct types of noise impacts: construction equipment noise and traffic noise from the cars and trucks that will travel along the routes to the tunnel and into the tunnel. The World Health Organization recognizes noise, and in particular traffic noise, as a serious public health problem.
b. Given the proposed tunnel construction and increased traffic after it opens, it is likely that the Project will result in significant noise impacts. In addition to identifying residences, the revised document should seek to identify all sensitive receptor sites including each motel and hotel, library, religious institution, hospital, nursing home, active sports area, picnic area, recreation area, playground, active sport area and park that would be potentially affected by noise from the additional traffic that will be on the I-710 Freeway between SR-60 and the approach to the tunnel, if that alternative is selected.
c. Given the serious nature of the Project's potential noise impacts, in conjunction with the effect that increased noise levels have been shown to have on public health, it is incumbent upon Caltrans through its DEIR/EIS to engage in a meticulous assessment of these potential impacts. The document's analysis of this issue, however, is subject to the same type of cursory analysis and critical omissions found in the DEIR/S overall.
a. On page 3.3-34, the Community Impact section of the DEIR/DEIS states that both Cal State LA and Marantha High School would experience permanent noise increases of 3dB if the tunnel is built. The DEIR/EIR also states that "based on a visual inspection of the exteriors of these facilities and the warm climate in the portion of Los Angeles County in which these facilities are located, the University and the high school are likely to rely on air conditioning in lieu of opening windows for ventilation; therefore the permanent noise level increases ... with the freeway tunnel alternative ... would not adversely affect their ability to serve the community." The DEIR/EIS community impacts report goes on to state that outdoor events at these two campuses would not be likely to be noise-sensitive because they "typically would produce their own noise." Noise analyses and impact determinations should not be made by "looking" at a school or site. Measurements of existing and estimated future noise impacts should be carefully considered and included in the DEIR/EIS and -- if these have not been done, they should be done and then be included in a revised and recirculated DEIR/EIS. This is a particularly egregious flaw in the DEIR/EIS: evaluating noise impacts through a "visual inspection" is simply unacceptable.

14. Noise mitigation measures are not included for the stretch of the I-710 Freeway between the SR-60 and the I-10, with the exception of noise barriers at a Golf Course and at a Park along the I-710 in this location.

a. A redone and recirculated DEIR/EIS must include noise analyses and noise mitigation measures for the stretch of the I-710 Freeway north of the SR-60 and south of the I-10, which includes East Los Angeles among other communities. This is an environmental justice issue.

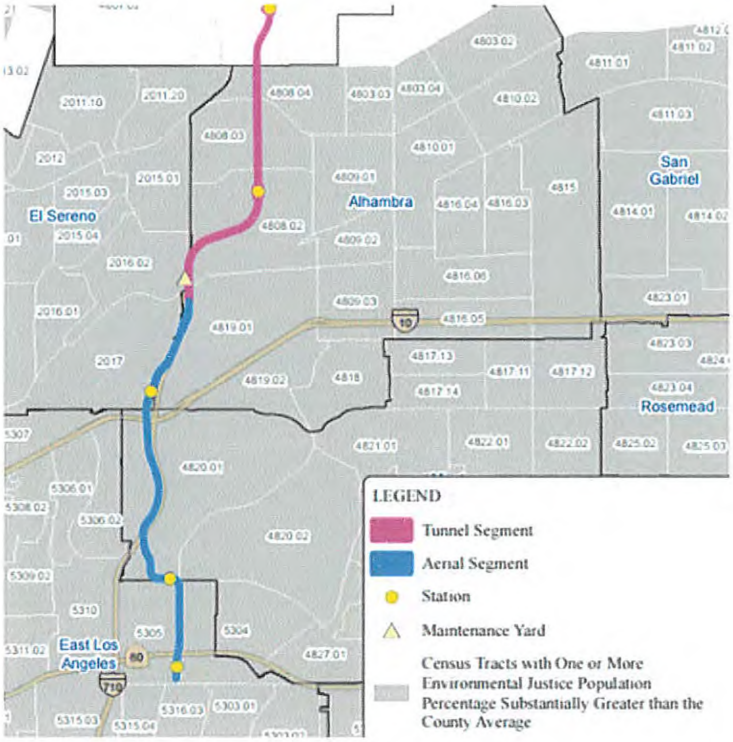
Maps 6 - 8. The noise mitigation area south of the I-10 along Corporate Center Drive, north of the SR-60, from the DEIR/EIS. *The shape includes a golf course in Monterey Park and an adjacent park both alongside Corporate Center Drive. No noise mitigation measures are described for any locations south of this location along the I-710 Freeway between the I-10 and the SR-60, despite the huge volumes of additional traffic there will be, from trucks alone, on this stretch of the Freeway as documented above:*



Map 6:

Map 7

Map 8

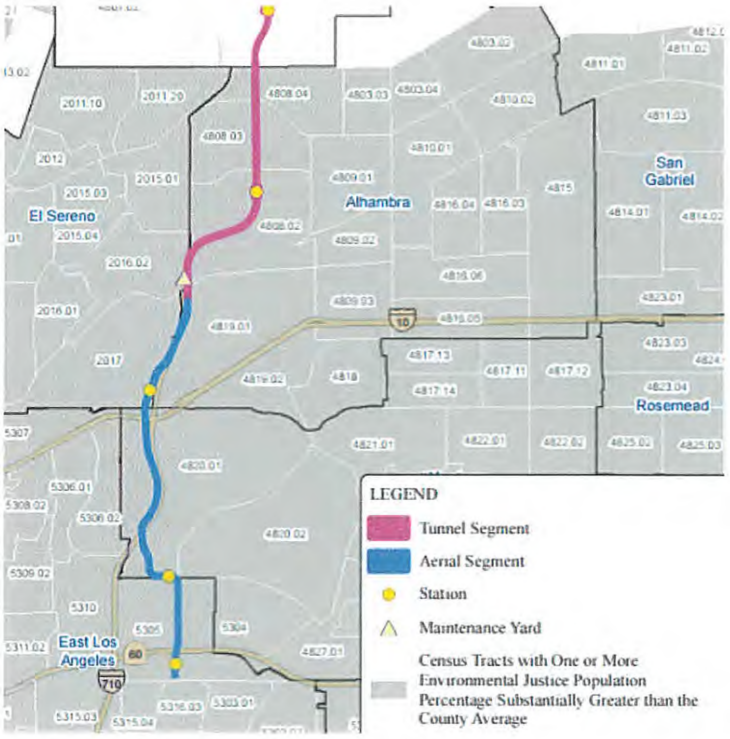


Blue oval = area of noise barrier mitigation near golf course and park

Red oval = area including East Los Angeles where no noise barriers are proposed despite the dramatic increase of truck traffic there will be in this stretch of the I-710.

15. **There are significant environmental justice issues from the various proposed alternatives, but these have been minimized by Caltrans even though various parts of East L.A. and El Sereno are documented in the DEIR/DEIS to have minority communities that would be disproportionately impacted.** Page 3.3-66/67 states that the Build Alternatives "would not cause disproportionately high and adverse effects on any minority or low-income populations under Executive Order 12898 regarding environmental justice." The graphic below shows the extent of the environmental justice population census tracts just in the area north of the SR-60 and South of the I-10 along the I-710 Freeway. An adequate I environmental justice analysis must be conducted and presented for review to the public.

Map 9.



Graphic from DEIR/EIS showing the census tracts with "environmental justice population percentage substantially greater than the county average.

10

16. **There was a clear lack of public participation and community outreach by Caltrans and Metro to East L.A. in the process of developing the Light Rail (LRT) Alternative.**
    a. This alternative appears to have been a surprise to many in East L.A., indicating a lack of community engagement by Caltrans on this alternative. There are significant environmental justice issues with the LRT alternative, such as (1) the LRT would be elevated in East L.A. but be in an underground tunnel in wealthier parts of the County, and (2) it would put an elevated rail line down a very popular street in East L.A. See map below.

Map 10. The Light Rail alternative would be "aerial" (elevated) (shown in blue below) in East L.A. and would be underground (pink) in other communities, including Pasadena.

b. Significant effects are identified in the DEIR/EIS about this alternative, which would displace numerous businesses and "adversely affect the community character and cohesion of this part of East L.A.," which we note is 97% Latino.
c. In addition, the LRT alternative would cause permanent noise level increases at the Roybal Comprehensive Center, Catholic Mission of Soledad Church, Soledad Enrichment Action, East L.A. Education Center and Casa Maravilla (East L.A.), as well as Cal State L.A. (See page 3.3-33 of the Community Impacts report).
d. Many aspects of including this alternative, the lack of community awareness about it, and selection of a location that would adversely affect community cohesion and community character, indicate insensitivities by Caltrans and Metro to the East L.A. Latino community – an environmental justice issue. If this alternative is selected, a new stand-alone DEIR/DEIS on this alternative should be developed that includes extensive consultation with the East L.A. community.

For the reasons documented above, we request that the DEIR/DEIS be redone and recirculated for public review. Thank you for your consideration of our comments.

‘LOS ANGELES’ RELOCATION GRAPHIC

Source: Pages 184 to 188 Relocation Impact Report, 2017 I-710 Recirculated Draft EIR/EIS

For every city facing the loss of property from the I-710 project along the corridor a report of the sales listings within the city was made except for East Los Angeles, instead they listed the following locations. Caltrans is by law required to make a report to show if there is enough available housing to relocate residents to. Why are East Los Angeles residents being treated differently than everyone else along the corridor?

90016 – 1 Listing | 90011 – 5 listings | 90003 - 5 | 90061 – 9 | 90001 - 14 Listings | **90002 - 48 Listings** | **90059 – 54 Listings** | 90048 - 1 Listings | 90026 – 2 Listings

90012 – 1 | 90065 – 7 Listings | 90042- 1 Listing | 90032 – 13 Listings | 90031 – 15 Listings | 90033 – 8 Listings | 90023 – 7 Listings (1 listing in East LA) | 90063 – 7 Listings | 90022 – 6 Listings

Only 14 of the 205 locations are actually in **East Los Angeles**. Approximately half of the listings are located in two adjacent zip codes – **90002 and 90059**.

Subject: Re: 710 EIR/EIS Extension 120 Days . . . ELA Public Hearing

Ms. Brown,

I concur with Mr. Torres. The 710 EIR has several options that will heavily impact the 250 merchants along the Whittier Blvd Shopping District. Not to mention the loss of parking along Atlantic, where shoppers will be forced to use Whittier Blvd for parking. I own 1427 S. Atlantic Blvd. I'll be moving soon to that location and my patients need parking. Due to physical challenges they cannot park far from the clinic. We are greatly impacted by these proposals and my organization also requests an extension and more public hearings.

IP-37-184

Please consider our request.

Sincerely and respectfully,

Dr. Victor Carabello
Owner of Medical Clinic at 1427 S. Atlantic Blvd LA 90022

Dear Ms. Brown,

On behalf of the East Los Angeles Chamber of Commerce we would like to make a formal request for the 710 EIR/EIS public comment period to be extended to 120 days. IP-37-186

Secondly, for the East Los Angeles Unincorporated to be given a public hearing at Humphreys Elementary which is located in the heart of the impacted area. Currently we believe the deadline is October 23, 2017. IP-37-187

Please take note all of the alternatives in the 710 EIR/EIS have a negative impact on East Los Angeles both business' and residence will be displaced. IP-37-188

Also the 710 EIR/EIS mentiones bus lanes on Atlantic Boulevard in the am and pm that would take away public parking from the business's, Schools, and Medical Clinics on Atlantic Boulevard.The 710 EIR/EIS also states there is ample parking on side streets of Atlantic Boulevard that could be used during these time periods. From our membership alone we know that some teachers from Fourth Street Elementary and Garfield High School, Kipp Charter School use Atlantic Boulevard for parking because there is very little or no parking available on the side streets located next to the school. IP-37-189

For instance, Kipp Charter School rents a basketball court from St. Alphonsus for parents to park in the AM and PM while they pick up their children. 2 medical facilities that we know of are trying to rent parking for their staff to free up parking for their patients also East L.A. Womens Clinic, Atlantic Tax Services, Chalio Restaurant, Broatman Auto Body, 99 Cent Plus Store, Tacos Mexico, Servano's Auto Repair, just to mention a few that depend on public parking available from the time that they open to closing time.The 710 ELA-LAC which East L.A. Chamber of Commerce (ELACOC) has been a part of since about 2002 was present at a 2015 presentation given by Cal-Trans and Metro. During the presentation the committee was asked for its support just to do an analysis on the effects to East L.A. by expanding the lanes from the 710 North that linked the 60 freeway East. ***I Eddie Torres, Chairperson of the ELACOC was told the analysis was only a survey for findings and that the understanding was Metro/Cal-Trans would come back to the 710 ELA-LAC at a later date and present the impacts through East Los Angeles. However, this was not the case. Our ELA-LAC committee was never invited and given a presentation of the findings or informed. We as a committee representing East L.A. were misled and left out of the loop until the recent 710 EIR/EIS document surfaced. Unlike other communities along the 710 alignment were invited by Cal-Trans and Metro to have meetings pertaining to the 710 project representing their committiees and their communities.*** The ELACOC/LAC do not have the resources to read and fully understand these documents. We feel it is only fair to provide us with an extension of time and an East L.A. Public Hearing. IP-37-190

Respectfully,

Eddie Torres, Chairperson

East Los Angeles Chamber of Commerce

Board of Directors

East Los Angeles Chamber of Commerce

Subject: Re: 710 EIR/EIS Extension 120 Days . . . ELA Public Hearing

I agree with the ELA Chamber of Commerce request, for 120 day extension. Also a public hearing in ELA also I am the Manager of Chalio Restaurant at 760 S Atlantic Blvd. we employed over 20 ELA residents. We have a small parking lot at the rear of the restaurant. We often have to have vehicles towed away, that are not our customers due to the lack of parking in Atlantic Blvd. By taking away Parking in Atlantic Blvd for any period of time would have a negative impact in all businesses. IP-37-191 IP-37-192

Respectfully,
Frank Mendez Chalio Manger

We as a committee representing East L.A. were misled and left out of the loop until the recent 710 EIR/EIS document surfaced. Unlike other communities along the 710 alignment were invited by Cal-Trans and Metro to have meetings pertaining to the 710 project representing their committiees and their communities.*** The ELACOC/LAC do not have the resources to read and fully understand these documents. We feel it is only fair to provide us with an extension of time and an East L.A. Public Hearing.

Subject: Re: 710 EIR/EIS Extension 120 Days . . . ELA Public Hearing

I Agree with Mr torres. As the owner of Irservices on 746 s Atlantic blvd. The parking on Atlantic is already difficult this would make it a nightmare. We would like to have our own public hearing to represent our interests in East LA. And also we need a 120 day comment period time extension.

If you have any questions plz contact me and ill give you an earful.

Ms. Brown,

I concur with Mr. Torres. The 710 EIR has several options that will heavily impact the 250 merchants along the Whittier Blvd Shopping District. Not to mention the loss of parking along Atlantic, where shoppers will be forced to use Whittier Blvd for parking. I own 1427 S. Atlantic Blvd. I'll be moving soon to that location and my patients need parking. Due to physical challenges they cannot park far from the clinic. We are greatly impacted by these proposals and my organization also requests an extension and more public hearings.

IP-37-199

Please consider our request.

Sincerely and respectfully,

Dr. Victor Carabello

On Sep 7, 2017, at 4:29 PM, Info Eastlachamber <info@eastlachamber.com> wrote:

Dear Ms. Brown,

On behalf of the East Los Angeles Chamber of Commerce we would like to make a formal request for the 710 EIR/EIS public comment period to be extended to 120 days. Secondly, for the East Los Angeles Unincorporated to be given a public hearing at Humphreys Elementary which is located in the heart of the impacted area. Currently we believe the deadline is October 23, 2017. Please take note all of the alternatives in the 710 EIR/EIS have a negative impact on East Los Angeles both business' and residence will be displaced. Also the 710 EIR/EIS mentiones bus lanes on Atlantic Boulevard in the am and pm that would take away public parking from the business's, Schools, and Medical Clinics on Atlantic Boulevard.The 710 EIR/EIS also states there is ample parking on side streets of Atlantic Boulevard that could be used during these time periods. From our membership alone we know that some teachers from Fourth Street Elementary and Garfield High School, Kipp Charter School use Atlantic Boulevard for parking because there is very little or no parking available on the side streets located next to the school. For instance, Kipp Charter School rents a basketball court from St. Alphonsus for parents to park in the AM and PM while they pick up their children. 2 medical facilities that we know of are trying to rent parking for their staff to free up parking for their patients also East L.A. Womens Clinic, Atlantic Tax Services, Chalio Restaurant, Broatman Auto Body, 99 Cent Plus Store, Tacos Mexico, Servano's Auto Repair, just to mention a few that depend on public parking available from the time that they open to closing time.The 710 ELA-LAC which East L.A. Chamber of Commerce (ELACOC) has been a part of since about 2002 was present at a 2015

IP-37-201

presentation given by Cal-Trans and Metro. During the presentation the committee was asked for its support just to do an analysis on the effects to East L.A. by expanding the lanes from the 710 North that linked the 60 freeway East. ***I Eddie Torres, Chairperson of the ELACOC was told the analysis was only a survey for findings and that the understanding was Metro/Cal-Trans would come back to the 710 ELA-LAC at a later date and present the impacts through East Los Angeles. However, this was not the case. Our ELA-LAC committee was never invited and given a presentation of the findings or informed. We as a committee representing East L.A. were misled and left out of the loop until the recent 710 EIR/EIS document surfaced. Unlike other communities along the 710 alignment were invited by Cal-Trans and Metro to have meetings pertaining to the 710 project representing their committiees and their communities.*** The ELACOC/LAC do not have the resources to read and fully understand these documents. We feel it is only fair to provide us with an extension of time and an East L.A. Public Hearing.

If you have received this message in error, please advise the sender immediately by reply email and delete this message. Thank you for your cooperation.

IP-37-1

Caltrans and Metro both respectfully disagree that the document is in violation of CEQA and/or NEPA. The analyses performed in support of the RDEIR/SDEIS followed Caltrans guidelines as established on the Caltrans Standard Environmental Reference. Environmental justice for all corridor cities and unincorporated areas, including East Los Angeles, is addressed within this document in Section 3.3.3, Environmental Justice, of the RDEIR/SDEIS.

IP-37-2

The commenter's opposition to Options 3A and 3B are acknowledged and included in the project record. Caltrans, as lead agency under CEQA and NEPA (as assigned by the Federal Highway Administration [FHWA]), in cooperation with the Los Angeles County Metropolitan Transportation Authority (Metro), has identified Alternative 1 (No Build) as the Preferred Alternative. Therefore, Design Option 3A is no longer under consideration, due in large part to community input. Please refer to Section 1.1 of this appendix for further discussion on the identification of the Preferred Alternative.

IP-37-3

Caltrans and Metro both respectfully disagree that any portion of the project development process or outreach effort was intended to preclude any persons from fully participating in the environmental process. It is true that both the release of the Draft EIR/EIS in 2012 and the RDEIR/SDEIS in 2017 took place in the summer; it is simply coincidental that this occurred for both iterations of the draft. Moreover, the release of the RDEIR/SDEIS occurred as soon as it was approved and signed by Caltrans. Please refer to Section 1.2 of this appendix regarding the length of the public comment period.

IP-37-4

In order to facilitate access to the documents to the greatest extent feasible, the Executive Summary was translated into Khmer, Korean, Spanish, Tagalog, and Vietnamese. Translation of the entire RDEIR/SDEIS was deemed infeasible. Please note that English is considered the language of record for the project.

IP-37-5

Please refer to Section 1.2 of this appendix regarding the extension of the public comment period.

IP-37-6

Because the community of East Los Angeles is an unincorporated area of Los Angeles County, the information contained in the County's parcel assessor lookup database (maps. assessor.lacounty.gov) lists addresses within unincorporated areas of the County as "Los Angeles." In order to clarify, the entries within Appendix L, Parcel Acquisitions Under Alternatives 5C and 7, have been clarified to more accurately describe their location for the reader. In addition, the number of displaced units and persons under either of the build alternatives has been clarified and corrected in the document where applicable.

IP-37-7

When the RDEIR/SDEIS was made available on the Caltrans website online, the comment link was initially located at the bottom of the page, following the various download links to the translated Executive Summary and technical studies. After feedback was received, a link to the comment submittal form was also placed at the top of the web page. Regarding the PDF of the document itself, the Project Team only received one complaint during the comment period that a user was initially unable to access the file. The PDF file itself was tested on several different computers and confirmed to be accessible shortly after it was made available to the public.

IP-37-8

The commenter is correct in that the online portal was not able to allow for attachments to be submitted. This is due to the inability to screen attachments for potential viruses, as well as the increased chance of errors occurring. Caltrans and Metro both respectfully disagree that residents of East Los Angeles, or any city or community in the project area, were unable to fully participate in the RDEIR/SDEIS public circulation process.

IP-37-9

The delineation of the general Study Area as illustrated on Figure 1.1-2 in the RDEIR/SDEIS best reflects an area wherein actual impacts of the proposed project may reasonably occur. As stated in Section 1.1 of the RDEIR/SDEIS, "The Study Area includes…all *or portions of* the Ports, the Cities… [italics added]". The community of East Los Angeles was not treated differently than any other corridor area city or community in this regard. It is also important to note that specific study areas have been established for individual environmental analyses (including, but not limited to, the health risk assessment zone of influence and the community impact assessment focus area). Caltrans and Metro both respectfully disagree that the delineation of the general Study Area precluded an accurate analysis of impacts or introduced any civil rights issues.

IP-37-10

Please refer to Response to Comment IP-37-9 regarding the delineation of the general Study Area. Caltrans and Metro acknowledge that the community of East Los Angeles is within both the I-710 Corridor Project and SR-710 North Project study areas and have included cumulative impacts analyses within both environmental documents.

IP-37-11

This comment states that the cumulative impacts on East Los Angeles from the SR-710 project should be assessed. Section 3.25 currently includes an assessment of cumulative impacts from each of the SR-710 North Project Build Alternatives (Project T-2 in Table 3.25-1), including those resulting from implementation of the TSM/TDM Alternative.

IP-37-12

Please refer to Response to Comment IP-37-9 regarding the delineation of the general Study Area. Environmental justice for East Los Angeles is addressed within Section 3.3.3, Environmental Justice, of the RDEIR/SDEIS. Air quality impacts to environmental justice communities were discussed in detail, including contour maps, in Section 3.3.3.5 of the RDEIR/SDEIS.

IP-37-13

Environmental justice for all corridor cities and communities, including East Los Angeles, is addressed within Section 3.3.3, Environmental Justice, of the RDEIR/SDEIS. In addition, the supporting Community Impact Assessment technical study took into account the entire unincorporated community of East Los Angeles. Each of the cities and communities within the I-710 Corridor Study Area were treated uniformly in the methodologies for each environmental analysis that was performed in support of the RDEIR/SDEIS. Caltrans has evaluated the environmental justice impacts of the project in accordance with standard procedures.

IP-37-14

Neither FHWA nor Caltrans currently has an approved methodology addressing the health impacts of freeways, and these types of assessments are an emerging practice in the transportation sector in the United States. Currently, State Departments of Transportation generally have not yet begun to implement HIAs or related tools for transportation planning, with some exceptions. For example, San Francisco's Department of Public Health has employed the use of HIAs in evaluating the health impacts of transportation projects. The State of Massachusetts passed a law requiring HIAs on new transportation projects, and at least one is known to be complete (the McGrath Highway Corridor HIA). In addition, Caltrans Division of Research and Innovation is actively investigating the use of HIAs for transportation planning and

potential applicability to Caltrans projects.[11] However, it should also be noted that there are limitations associated with the preparation and use of Health Impact Assessments. According to an article published in 2000 in the British Medical Journal, "Currently there is neither an accepted gold standard nor even a simple, reliable, and evaluated method for carrying out health impact assessment" and "Several issues are unresolved in the methodology of health impact assessment…causal pathways are so complex that it is not often possible to say if an outcome will definitely be good or bad for the health of a population…The current evidence base for many health determinants is inadequate for accurately informing a process of assessment."[12] Hence, the preparation of an Air Quality/Health Risk Assessment for the I-710 Corridor Project was an effort to respond to the requests of the I-710 Corridor communities to study health-related impacts, while also ensuring the empirical analyses performed in support of the EIR/EIS process are factual and based on sound scientific, analytical, and/or engineering judgment.

IP-37-15

Environmental justice for all corridor cities and communities, including East Los Angeles, is addressed within Section 3.3.3, Environmental Justice, of the RDEIR/SDEIS. Impacts to environmental justice populations are discussed in Section 3.3.3.5, Environmental Consequences. The build alternatives propose Measure C-7, where, should a build alternative be selected as the Preferred Alternative, East Los Angeles would be eligible for funding that would be provided to local jurisdictions for targeted improvements that would improve air quality and public health, reduce traffic congestion, provide aesthetic/visual enhancements, and improve parks and recreation. Please refer to Section 3.3.3.7 for more detailed information regarding this measure. However, as stated in Response to Comment IP-37-2, the No Build Alternative has been selected as the Preferred Alternative. Therefore, Measure C-7 will not be implemented.

IP-37-16

It is unclear how the commenter feels that the analysis included in Section 3.3.3 of the RDEIR/SDEIS did not address disproportionate impacts to low-income and minority communities in a meaningful manner. Measure C-7 is proposed to specifically address disproportionate impacts to environmental justice populations with regards to air quality, traffic, visual impacts, and land use/parks and recreation resulting from the build alternatives. Should a build alternative be selected as the Preferred Alternative, funding would be provided to local jurisdictions for targeted

[11] Caltrans Division of Research and Innovation. Preliminary Investigation. 2011. Transportation-Related Use of Health Impact Assessments and Similar Tools. August 5, 2011. Website: http://www.dot.ca.gov/research/researchreports/preliminary_investigations/docs/public_healthpreliminary_investigation_8-5-11_revised.pdf (accessed June 25, 2018).

[12] U.S. National Library of Medicine National Institutes of Health. Health Impact Assessment. May 20, 2000. Website: https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1118057/ (accessed June 28, 2018).

improvements that would improve air quality and public health, reduce traffic congestion, provide aesthetic/visual enhancements, and improve parks and recreation in environmental justice communities. Please refer to Section 3.3.3.7 for more detailed information regarding this measure. However, as stated in Response to Comment IP-37-2, the No Build Alternative has been selected as the Preferred Alternative. Therefore, Measure C-7 will not be implemented.

IP-37-17

Please refer to Section 1.1 of this appendix for more information regarding the identification of the Preferred Alternative. Options 3A and 3B are no longer under consideration. However, removal of alternatives and options from consideration are not triggers that would necessitate revision and recirculation of the EIR/EIS.

IP-37-18

Caltrans has not established, and has no intention to establish, CEQA thresholds, and NEPA does not have specific standards for each resource area. CEQA requires the disclosure and mitigation of significant impacts of a proposed project, and NEPA requires the assessment and disclosure of the environmental effects of proposed actions. The effects of the build alternatives, and measures to avoid, minimize, or mitigate those effects, were presented in the RDEIR/SDEIS. Therefore, Caltrans and Metro both respectfully disagree that the RDEIR/SDEIS violated CEQA or NEPA standards. Environmental justice for all corridor cities and communities, including East Los Angeles, is addressed within Section 3.3.3, Environmental Justice, of the RDEIR/SDEIS.

IP-37-19

The potential cumulative impacts of the I-710 Corridor Project and the SR-710 North Project are disclosed in the Cumulative Impacts section of each respective environmental document. Therefore, a stand-alone study is not necessary and would not introduce any new information.

IP-37-20

Please refer to Response to Comment IP-37-14 regarding a Health Impact Assessment.

IP-37-21

The commenter’s opposition to Design Options 3A and 3B are acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative and does not incorporate Design Option 3A, and therefore, would not result in the displacement of residents or business. Appendix L, Parcel Acquisitions Under Alternatives 5C and 7, in this Final EIR/EIS contains a list of full or partial acquisitions and the relative displacement for each build alternative.

IP-37-22

The commenter's opposition to the displacement of families in East Los Angeles as a result of Design Options 3A and 3B are acknowledged and included in the project record. Please refer to Response to Comment IP-37-21 regarding the displacement of residents or businesses.

IP-37-23

The commenter's concern regarding homelessness and high rent rates in Los Angeles are acknowledged and included in the project record. The Preferred Alternative (Alternative 1 No Build), which does not incorporate Design Option 3A, will not result in the relocation of residents within East Los Angeles.

IP-37-24

As stated in Response to Comment IP-37-2, the No Build Alternative has been selected as the Preferred Alternative. Therefore, there will be no displacements or relocations.

IP-37-25

It is important to note that there would be no displacements of businesses or residents within East Los Angeles as a result of the Preferred Alternative. However, the replacements area for the build alternatives included the displacement communities as well as adjacent cities and communities along the I-710 Corridor. The search for replacement housing was confined to this replacement area, and did not include (for example) the entire City of Los Angeles. The replacement area map included as Appendix A to the *Draft Relocation Impact Report* (March 2017) shows the location of potential replacement sites along the I-710 Corridor. The community of East Los Angeles was included on the replacement area map as a portion of unincorporated Los Angeles County and a number of potential replacement sites were identified within East Los Angeles. Appendix E to the *Draft Relocation Impact Report* listed specific replacement dwellings for sale and for lease and included a number of potential replacement residences within the three zip codes that comprise East Los Angeles.

IP-37-26

Caltrans and Metro thank the commenter for this information, and the agencies regret the error. The property located at 626 S. Sydney Dr. in East Los Angeles was originally identified as being a five-unit property in the *Draft Relocation Impact Report* (March 2017) and the RDEIR/SDEIS; however, the property contains ten units. This information has been acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative. Therefore, no displacement of residents or businesses from the community of East Los Angeles will occur under the Preferred Alternative.

IP-37-27

Caltrans and Metro respectfully disagree that the RDEIR/SDEIS was deficient in analyzing impacts to East Los Angeles. The housing stock provided in the *Draft Relocation Impact Report* (March 2017) is an estimate based on the most currently available information at the time the RDEIR/SDEIS was prepared. It is important to note that Design Options 3A and 3B have been withdrawn from consideration. Under the Preferred Alternative (Alternative 1 No Build), no residential or business displacements would occur within East Los Angeles. Please also refer to Section 1.6 of this appendix for more information regarding the replacement area methodology used in the *Draft Relocation Impact Report*.

IP-37-28

As stated in Section 2.3.3.3 of the RDEIR/SDEIS, Design Options 3A and 3B extend from the north of the Washington Blvd., interchange to the SR-60 interchange, which is a distance of approximately two miles through the City of Commerce and the unincorporated areas of East Los Angeles. The traffic volumes travelling through the I-710 Corridor in Design Options 3A and 3B would be similar to those in respective Alternatives 5C and 7, the only difference being that they are configured differently. Thus, localized air quality and health risk impacts of Design Options 3A and 3B would be similar or lower than the respective Alternatives 5C and 7 because (1) overall traffic levels and emissions would be similar for the design options and related build alternatives (5C or 7), (2) the traffic in Design Options 3A and 3B would be spread out over a larger geographic area as compared to Alternatives 5C and 7 (i.e., lower emissions density), and (3) freeway mainline emissions would dominate local impacts. Design Options 3A and 3B were not selected by the Metro Board to be carried forward as part of the Preferred Alternative.

IP-37-29

Two design options were examined in the RDEIR/SDEIS that would modify local access to I-710 in the East Los Angeles area. Design Options 3A and 3B would limit access to I-710 in the northbound direction from the Olympic Blvd. on-ramp and would shift the ramp termini from I-710 in the southbound direction from Eastern Ave. to Whittier Blvd.

The detailed information included in the *I-710 Corridor Project Traffic Operations Analysis Report* (March 2017) and the *Intersection Traffic Impact Analysis Report* (March 2017) evaluated the effects that these modifications would have on twenty-four intersections examined on the local circulation network in East Los Angeles, which is surrounded by I-5, I-710 and SR-60. This information regarding the impacts of the Design Options was also summarized in Section 3.5.3 of the RDEIR/SDEIS. These effects, along with concerns related to community as well as right-of-way impacts, were considered along with public comments on the alternatives and design options evaluated in the RDEIR/SDEIS. As a result, Design Options 3A and 3B were removed from further consideration.

IP-37-30

Options 3A and 3B have been removed from further consideration. Please refer to Response to Comment IP-37-28 for a discussion on why localized air quality and health risk impacts of Design Options 3A and 3B would be expected to be similar or lower than the respective build Alternatives 5C and 7.

As described in Section ES.6.1 of the AQ/GHG/HRA Technical Study, the future (2035) build alternatives would reduce cancer risk as compared to the 2012 Baseline. These reductions would be a result of the cleaner diesel trucks as required by California Air Resources Board's (CARB) Truck and Bus rule and implementation of the Clean Trucks Program by the Port of Los Angeles and Port of Long Beach. The slight increases in health risk referred to in the comment refer to the comparisons of the 2035 build alternatives to the 2035 No Build Alternative. As stated in Section 8 of Appendix D to the AQ/GHG/HRA Technical Study, receptors for the Health Risk Assessment were placed as close as 150 feet from the edge of the mainline right-of-way. Receptors at this distance are fully consistent with (and in many cases, closer than) recent analyses of Port, railyard and other transportation projects in Southern California.

Impacts related to noise are described in detail in Section 3.14. The Preferred Alternative, Alternative 1 (No Build), does not include any elevated truck lanes and thereby would not produce noise impacts to residents from the elevated structures. Alternative 7 would use elevated truck lanes, and a discussion of proposed soundwall locations (including those in East Los Angeles, is provided in Section 3.14.5, Noise Abatement Considerations). However, as stated in Response to Comment IP-37-2, the No Build Alternative has been selected as the Preferred Alternative. Therefore, noise abatement will not be implemented.

IP-37-31

Please refer to Response to Comment IP-37-29 regarding the traffic analysis conducted for the I-710 Corridor Project.

IP-37-32

Access to and from Eastern Ave. would not be changed as a part of the Preferred Alternative (Alternative 1 No Build), which does not include Design Option 3A. Therefore, there will not be any conflict between the freeway improvements and any proposed pathway at Calvary Cemetery.

IP-37-33

The intersection of Eastern Ave. and Eagle St. in East Los Angeles is not within the jurisdiction of Caltrans or Metro. The commenter is encouraged to contact the Los Angeles County Department of Public Works at www.dpw.lacounty.gov or (626) 458-5100.

IP-37-34

Under Design Options 3A and 3B, vehicles traveling southbound on I-710 from SR-60 would still be able to access southbound I-5 in the same manner as is presently available. However, since the No Build Alternative has been selected as the Preferred Alternative, Design Options 3A and 3B have been withdrawn from consideration and no further analysis on these design options is necessary.

IP-37-35

Please refer to Response to Comment IP-37-29 regarding the traffic analysis conducted for the I-710 Corridor Project.

IP-37-36

Please refer to Response to Comment IP-37-29 regarding the traffic analysis conducted for the I-710 Corridor Project.

IP-37-37

Please refer to Response to Comment IP-37-2 regarding Design Option 3A.

IP-37-38

Please refer to Response to Comment IP-37-2 regarding Design Option 3A.

IP-37-39

Please refer to Response to Comment IP-37-2 regarding Design Option 3A.

IP-37-40

As discussed in Section 1.2.2 in Chapter 1.0, Proposed Project, of the RDEIR/SDEIS, one of the purposes of the project is to improve air quality and public health. As discussed in Section 3.13, Air Quality, in the RDEIR/SDEIS, all build alternatives would generally improve air quality and reduce public health risk. Along I-710, air quality would be improved and public health risk would be reduced at most locations, but there would be a few near-roadway locations where there would be an increase in certain emissions. The increase in health risk resulting from increased

emissions was analyzed in the AQ/GHG/HRA Technical Study and summarized in Section 3.13, Air Quality, of the RDEIR/SDEIS. As detailed in the AQ/GHG/HRA Technical Study, the health risk assessment was conducted using a methodology that is consistent with the California Environmental Protection Agency (Cal/EPA) Office of Environmental Health Hazard Assessment (OEHHA) Air Toxics Hot Spots Program Risk Assessment guidance and the SCAQMD Risk Assessment Guidelines for Assembly Bill 2588.

As discussed in Section 3.13 of the RDEIR/SDEIS, the increase in emissions would not increase cancer risk compared to the 2012 Baseline. When compared to the 2035 No Build Alternative, both build alternatives would reduce cancer risk at most locations; however, a small increase in cancer risk would occur at some locations within 100 meters of I-710. For Alternative 5C, the maximum increase in risk would be approximately three in one million. The primary location of the increased risk for Alternative 5C would occur along a small portion of I-710 just south of SR-60. For Alternative 7, the increase in risk would be less than one in one million.

The build alternatives propose Measures AQ-2 and AQ-3 to further reduce exposure to emissions at near-roadway locations. Should a build alternative be selected as the Preferred Alternative, Measure AQ-2 would provide for installation of air filtration systems for schools within 0.25 mile of I-710, including Humphreys Avenue Elementary School. Measure AQ-3 would require installation of solid barriers and installation of vegetation where soundwalls are not proposed to disperse pollution and reduce pollutant concentrations downwind. Additionally, the build alternatives include programmatic components to help improve air quality and public health in the I-710 Corridor. The I-710 Corridor Community Health Benefit Program would be a programmatic component of the build alternatives and would take the form of a grant program structured to provide corridor communities the opportunity to implement projects or outreach activities that would improve air quality and public health related to I-710 travel and goods movement. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more information regarding the Community Health Benefit Program.

The RDEIR/SDEIS complies with the NEPA requirement that a project must evaluate impacts to environmental justice populations and develop mitigation measures specifically to address potential disproportionately high and adverse effects to minority and/or low-income communities. As discussed in Section 3.3.3, Environmental Justice, of the RDEIR/SDEIS, although there are air quality benefits associated with the build alternatives, and these benefits would be experienced by the environmental justice populations that predominantly reside near the I-710 freeway, there would also be near-roadway adverse impacts that would disproportionately burden environmental justice populations. The build alternatives propose Measures AQ-2 and AQ-3 that would reduce exposure of environmental justice to populations to increases in air pollutant concentrations, should a build alternative be selected as the Preferred Alternative. However, even when

considering these mitigation measures in addition to the beneficial effects of the build alternatives on air quality and public health, both build alternatives could potentially have an adverse and disproportionate air quality impact to environmental justice populations in localized areas within the I-710 Corridor. Therefore, Measure C-7 was included in the RDEIR/SDEIS to further reduce air quality impacts to environmental justice populations resulting from the build alternatives. Should a build alternative be selected as the Preferred Alternative, Measure C-7 would provide funding for targeted improvements that would improve air quality and public health, and would include (but would not be limited to) the installation or upgrade of filtration systems along I-710. However, as stated in Response to Comment IP-37-2, the No Build Alternative has been selected as the Preferred Alternative. Therefore, Measure C-7 will not be implemented.

IP-37-41

Please refer to Response to Comment IP-37-14 for more information regarding Health Impact Assessments.

IP-37-42

A qualitative analysis of ultrafine particulates (UFP) was included in Section 3.13.3.4, Air Quality, of the RDEIR/SDEIS. It is important to note that UFPs are not currently regulated in the United States. Section 3.13.3.4 indicated that "information on UFP is limited at this time and is an area of active research…the existing state of knowledge does not yet support the derivation of reliable UFP emission models that account for the particulate growth and accumulation phases. Dispersion modeling of UFPs would also require additional information on the rate of UFP coagulation and absorption so that concentrations can be calculated. Given the lack of information to quantify emissions, dispersion, exposure, and health response to exposure, UFP emissions could not be quantified from the proposed project. However, a qualitative analysis has been conducted by using $PM_{2.5}$ exhaust emissions, and exposure as a surrogate for UFP exposure to assess the incremental impacts of the project alternatives as compared to the baselines." The near-roadway modeling indicated that implementation of either build alternative would decrease the public's health risk due to UFP relative to the 2012 Baseline and 2035 No Build Alternative, even near the I-710 freeway and/or freight corridor. However, as noted above, the No Build Alternative has been selected as the Preferred Alternative and the decrease in the public's health risk from the build alternatives would not be realized. Please refer to Section 3.13.3.4 of this Final EIR/EIS for further details on the qualitative analysis.

IP-37-43

Design Options 3A and 3B have been removed from consideration; therefore, the impacts cited in this comment would not occur. No further analysis is necessary.

IP-37-44

Design Options 3A and 3B have been withdrawn from consideration; therefore, the impacts cited in this comment would not occur. No further analysis is necessary.

IP-37-45

The commenter's opposition to Design Options 3A and 3B due to health impacts are acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative, and Design Option 3A has been removed from further consideration. Since the No Build Alternative has been selected as the Preferred Alternative, 946 S. Eastern Ave. where the DaVita Doctors Dialysis Center is located, will not be acquired.

IP-37-46

The build alternatives propose Measure AQ-1, as described in Section 3.13.4 of this Final EIR/EIS, which would require a funding contribution to be provided to the South Coast Air Quality Management District (SCAQMD) for the design and construction of four new air quality monitoring stations within the I-710 Corridor. Should a build alternative be selected as the Preferred Alternative, the specific locations of each monitoring station would be determined in coordination with SCAQMD, as the agency tasked with regulation and monitoring of air pollution; therefore, a specific commitment to a location or locations could not be made at the time the RDEIR/SDEIS was circulated for public review. Additionally, many of the 13 locations specified in this comment are within a mile of each other. Since the No Build Alternative has been selected as the Preferred Alternative, Measure AQ-1 will not be implemented. It should be noted that there are only 26 air quality monitoring sites within Los Angeles County (according to the California Air Resources Board[13]) and locations for sites are based on criteria including, but not limited to, spatial proximity to pollutant emissions sources, topography, wind direction, purpose of the monitoring, and others.

IP-37-47

Construction impacts from the build alternatives are discussed in detail in Section 3.24 of the RDEIR/SDEIS. Measures to address construction-related air pollution and noise resulting from the build alternatives are specifically discussed in Sections 3.24.4.13 and 3.24.4.14, respectively. Design Options 3A and 3B are no longer under consideration. Please also refer to Section 1.1 of this appendix for more information on the identification of the Preferred Alternative.

[13] CARB. 2018. Quality Assurance Air Monitoring Sites by County. Website: https://www.arb.ca.gov/qaweb/countyselect.php?c_arb_code=70 (accessed August 29, 2018).

IP-37-48

The potential for lead in soils was addressed in Section 3.12, Hazardous Waste, of the RDEIR/SDEIS, including measures to avoid and minimize exposure to lead resulting from the build alternatives. Environmental Data Resources, Inc. (EDR) was subcontracted to conduct a search limited to within a one-mile radius (i.e., ASTM International [ASTM] standard) of the I-710 Corridor Project build alternatives for facilities listed by regulatory agencies as potentially having environmental concerns. Additional readily accessible agency online databases were reviewed, including the California Department of Resources Recycling and Recovery (CalRecycle); Solid Waste Information System (SWIS); the California Department of Toxic Substance Control (DTSC) ENVIROSTOR database; and the State Water Resources Control Board's (SWRCB) GeoTracker database. The sites listed in Tables 3.12.1, 3.12.2, and 3.12.3 are sites identified as posing potential environmental concerns. The Exide Technologies, Inc. (Exide) battery recycling facility at 2700 S Indiana St., Vernon, CA 90058 (closed since 2015) is not listed in these tables because the facility was not within nor adjacent to any of the properties that would be acquired for the build alternatives. The DTSC is responsible for overseeing the cleanup of properties affected by contamination from the Exide facility. The most recent map of the cleanup area posted on the DTSC website (https://dtsc.maps.arcgis.com/apps/webappviewer/index.html?id=d8a6b586685f46f793e39759c71be3ef; accessed January 3, 2023) shows the status of the site assessment and cleanup of properties within the Preliminary Investigation Area for the Exide facility adjacent to I-710. None of these properties will be fully or partially acquired for the Preferred Alternative (Alternative 1 No Build).

IP-37-49

Refer to Section 3.24.3.4, Utilities/Emergency Services, which describes impacts to fire stations located within 0.5 mile of the general I-710 Study Area. In addition, the build alternatives propose Measure CON-U&ES-1 which states that prior to and during construction of either build alternative, Caltrans and the Construction Contractor would coordinate all temporary ramp closures and detour plans with fire providers to minimize temporary delays to emergency response times as part of the TMP, including the identification of alternative routes and routes across the construction areas for emergency vehicles, developed in coordination with the affected agencies. The likelihood of a natural disaster occurring that may prevent access to and from a fire department or other emergency service provider facility is beyond the scope of a project-level CEQA/NEPA environmental document, and as such, was not evaluated within the RDEIR/SDEIS. It is important to note that since the No Build Alternative has been selected as the Preferred Alternative, Measure CON-U&ES-1 will not be implemented.

IP-37-50

According to the traffic model, the Level of Service (LOS) designation on I-710 between I-5 and SR-60 would not change, should a build alternative be selected as the preferred Alternative. In

East Los Angeles, this section of I-710 is predicted to operate at LOS F under the future (2035) No Build Alternative. Under the build alternatives, this segment of I-710 would remain LOS F in 2035. However, given the severity of traffic congestion throughout the metropolitan region, there are different gradients of LOS F that can be quantified using alternative means. VISSIM traffic modeling software was utilized as an additional analysis tool for the highway capacity analysis to examine congestion bottlenecks in key areas along the I-710 Corridor for the p.m. peak hour in order to help inform the design during development of the build alternatives. This VISSIM analysis showed that the auxiliary lanes included in the design of the build alternatives would relieve the congestion bottleneck between I-5 and SR-60, but only slightly.

While delay for some of the local intersections would improve as a result of the build alternatives, and delay at others would decline slightly, the overall purpose of the intersection impact analysis was to identify significant adverse impacts within the I-710 Study Area. A few seconds of delay for an intersection that is already performing at LOS D or better is not considered a significant adverse impact. A significant adverse impact would occur if the level of service degrades to LOS E. Similarly, a few seconds decrease in delay for an intersection would not be considered a noticeable, beneficial improvement. These impact thresholds are described in detail at the beginning of Section 7 in the *Intersection Traffic Impact Analysis Report* (2017) and summarized in Section 4.2.4.4 of the RDEIR/SDEIS. The purpose of the traffic mitigation measure (Measure TR-1) proposed for the build alternatives would be to address the adverse impacts of the build alternatives for those intersections that would be *significantly* impacted by returning them to future No Build (Alternative 1) traffic conditions or better.

Additionally, the I-710 Congestion Relief Program is a programmatic feature of the build alternatives that would be targeted towards improving congested intersections on the arterial system in East Los Angeles under future year (2035) travel conditions. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway.

IP-37-51

The main purpose of the proposed freeway improvements included in the build alternatives are to address congestion, design deficiencies, traffic operations, and safety concerns on I-710, as well as related air quality issues associated with operation of the I-710 freeway, as discussed in more detail in Section 1.2 of the RDEIR/SDEIS. Over 185 intersections were evaluated as part of the traffic analysis to determine if the build alternatives would result in traffic impacts to the arterial system, and if so, to identify measures to address these impacts. The number and locations of the study intersections were identified prior to the initiation of the traffic studies performed for the RDEIR/SDEIS, and were reviewed and approved by the I-710 Technical Advisory Committee. Approximately 24 of these selected intersections are located within East Los Angeles, more than

any other local jurisdiction in the I-710 Study Area, with the exception of the City of Long Beach. Nearly half of the I-710 Corridor is located in the City of Long Beach. Traffic counts were obtained for all 24 of these intersections.

IP-37-52

In East Los Angeles, the section of I-710 between I-5 and SR-60 would operate at Level of Service (LOS) F under the future No Build Alternative. Under the build alternatives in 2035, this segment of I-710 would remain LOS F. However, given the severity of traffic congestion throughout the metropolitan region, there are different gradients of LOS F that can be quantified using alternative means. VISSIM traffic modeling software was utilized as an additional analysis tool to examine congestion bottlenecks in key areas along the I-710 Corridor for the p.m. peak hour in order to help inform the design during development of the build alternatives. This VISSIM analysis showed that the auxiliary lanes included in the build alternatives would relieve the congestion bottleneck between I-5 and SR-60 to some extent. Vehicle density would be reduced and freeway speeds would still be low, but would improve by 3 mph in the southbound direction and 12 mph in the northbound direction under Alternative 5C relative to the future No Build Alternative in this congestion hot spot location. In addition, Tables 5-1, 5-2, 5-7, and 5-8 provided in the *I-710 Corridor Project Traffic Operations Analysis Report* (March 2017) demonstrate that levels of service on I-710 north of SR-60 would not be affected by implementation of Alternative 5C. However, as shown in Tables 5-1, 5-2, 5-10, and 5-11 provided in the *I-710 Corridor Project Traffic Operations Analysis Report* (March 2017), levels of service on I-710 north of SR-60 under Alternative 7 would be slightly worse in the northbound direction during the PM peak hour and slightly higher in the southbound direction during the AM and midday peak hours. However, as stated previously, the No Build Alternative has been selected as the Preferred Alternative and this impact under Alternative 7 would not occur. It should be noted that Design Options 3A and 3B are no longer under consideration.

When capacity is added to freeways, traffic volumes on the freeways increase as motorists shift routes to take advantage of the improved travel conditions offered by the capacity increase. While some of this traffic may represent new vehicle trips, much of the observed increase in traffic comes from trips that were already being made before the increase in highway capacity, or reflect predictable behavior that is accounted for in travel demand forecasts. “Induced travel” is characterized as the additional demand for travel that occurs as a result of a decrease in the generalized cost of travel, including both travel-time and out-of-pocket costs. I-710 is part of a highly congested metropolitan roadway network and is located within an urbanized area, which is essentially built out. Given the high levels of congestion in the peak periods, the I-710 travel demand forecast model is particularly sensitive to changes in travel times. The proposed improvements included in the build alternatives would improve speeds and would reduce travel times on I-710, which in turn would attract more traffic to the facility relative to the No Build Alternative. The modernization of the current freeway design proposed as part of the build

alternatives would improve traffic operations and safety, and the traffic analysis summarized in Section 3.5 of the RDEIR/SDEIS showed that even carrying higher traffic volumes than the No Build Alternative, the build alternatives would provide an overall improved Level of Service (LOS) within the I-710 Corridor, which is indicative of reduced traffic congestion. The predicted shifts in traffic were accounted for in the analysis presented in Section 3.5 of the RDEIR/SDEIS for both Alternatives 5C and 7.

IP-37-53

The traffic volumes on I-710 through East Los Angeles would increase for both build alternatives as compared to the No Build Alternative. The vehicle miles traveled (VMT) on the I-710 Corridor in East Los Angeles would increase as well. The build alternatives include programmatic funding for ZE/NZE heavy-duty trucks that travel on I-710, and it is forecast that about one-third of the future heavy-duty truck volume on I-710 through East Los Angeles would be comprised of these ZE/NZE trucks. The RDEIR/SDEIS disclosed the associated air quality and noise effects in East Los Angeles from the increased traffic volumes associated with these alternatives, along with the effects of these alternatives on local mobility, in Sections 3.13, 3.14, and 3.5, respectively.

IP-37-54

There is no existing off ramp from I-710 to 3rd St. in the southbound direction. However, there is an on-ramp from 3rd St. to southbound I-710 in East Los Angeles. The closure of this existing on-ramp was not considered as part of the build alternatives as it would eliminate an important access point for East Los Angeles residents in an area that already has limited access to the freeway system within this triangular portion of East Los Angeles that is bounded by the I-5, SR-60, and I-710.

IP-37-55

Although these suggestions are innovative, Caltrans and Metro do not have the authority to mandate that employers offer the incentives to encourage employees to use public transportation, utilize zip line programs, move closer to work, commute during off-peak hours, or telecommute. It is the discretion of each individual employer to decide what incentives they want to offer employees. Additionally, transportation funds earmarked for roadway improvements cannot be diverted to fund these types of incentives which should funded by each individual employer.

IP-37-56

Metro currently has programs in place to encourage carpooling and to provide reduced fares to eligible applicants. The Metro commuter and employer rideshare programs assist drivers with finding people to carpool with and provides full assistance to employers for Average Vehicle Rider (AVR) reports, ride-matching services, and marketing workshops. More information on the Metro

ride share program can be accessed at https://www.metro.net/riding/rideshare/. The Metro reduced fares program provides discounted Metro passes, transit subsidies, and reduced group rates to employers. More information on the Metro reduced rates program can be accessed at https://www.metro.net/riding/fares/reduced-fares/. Caltrans and Metro have no authority to mandate that people and employers take advantage of the programs that are already in place to encourage ridesharing and use of transit.

IP-37-57

As noted in the comment, there are already programs in place in Los Angeles County for drivers to replace their vehicle with less polluting models. In the Los Angeles area, the program is known as Replace Your Ride. Caltrans and Metro have no authority to mandate that people take advantage of the programs that are already in place to encourage replacement of older vehicles with newer, less polluting models.

IP-37-58

Caltrans and Metro strive to develop and present the most appropriate avoidance, minimization and/or mitigation measures taking into consideration right-of-way constraints, safety, and feasibility in implementing any proposed mitigation for the build alternatives. In general, left-turning vehicles would experience more delay when they are waiting for sufficient gaps in the on-coming traffic to clear the intersection, which would create long queues. By providing an exclusive left-turn lane and by separating these left-turn vehicles from through traffic, these queues would now be shorter, and the safety and delay for the intersection as a whole (i.e., all approaches) would be improved. Therefore, the average total delay at the intersection would be reduced and level of service for the intersection would improve. The Synchro analysis conducted for this intersection demonstrated that this intersection would be improved by adding an exclusive left-turn lane. These detailed LOS analysis worksheets were provided in the appendices to the *Intersection Traffic Impact Analysis Report* (March 2017). In addition, the delay at this intersection under Alternative 5C would not be as severe as what would occur under Alternative 7, which was an additional factor to consider when viewing the pre- and post-mitigation traffic analysis results.

IP-37-59

The overall intersection delay as reported would be a combination of the average delay for all approaches. By reducing the approach delays for the north and southbound directions, the overall intersection delay would be reduced as well, since the amount of “green time” would now be optimized for all approaches. By adding an exclusive left-turn lane on the northbound and southbound approaches, the total delay at the intersection could be reduced to better than what was projected under the 2035 No Build Alternative.

IP-37-60

In general, left-turning vehicles would experience more delay waiting for sufficient gaps in the on-coming traffic to clear the intersection. It is true that when a through lane is shared with a right-turn lane, sometimes right-turning traffic blocks through traffic while waiting for pedestrians to cross the street on a green. However, right-turning vehicles are permitted to turn right on red signal unless they are specifically prohibited from doing so. By making legal right turns on a red signal, those vehicles would avoid pedestrians in the crosswalk, who are prohibited from crossing on a red, and thus help clear the overall intersection by leaving more “green time” for through traffic.

IP-37-61

Measure TR-1 would, should a build alternative be selected as the Preferred Alternative, take into consideration right-of-way constraints, safety, and feasibility in implementing any proposed mitigation. In general, left-turning vehicles experience more delay when they are waiting for sufficient gaps in the on-coming traffic to clear the intersection, creating long queues. By providing an exclusive left-turn lane and by separating these left-turn vehicles from through traffic, these queues would now be shorter, and the safety and delay for the intersection as a whole (i.e., all approaches) would be improved. Therefore, the average total delay at the intersection would be reduced and level of service for the intersection would improve. The Synchro analysis conducted for this intersection demonstrated that this intersection would be improved by adding an exclusive left-turn lane. These detailed LOS analysis worksheets were provided in the appendices to the *Intersection Traffic Impact Analysis Report* (March 2017).

IP-37-62

The proposed improvements at this intersection as described in Measure TR-1 would improve traffic operations and reduce queues resulting from the build alternatives. There would not be any need to move the bus stop from its current location. It is important to note that since the No Build Alternative has been selected as the Preferred Alternative, Measure TR-1 will not be implemented.

IP-37-63

The overall intersection delay as reported is a combination of the average delay for all approaches. By reducing the approach delays for the north and southbound directions, the overall intersection delay would be reduced as well. Should a build alternative be selected as the Preferred Alternative, Measure TR-1 identified in Section 3.5.4 of the RDEIR/SDEIS would aim to improve the impacted intersection delay from poor operating conditions (LOS E or F) under the build alternatives to a level equal to or better than the LOS projected for the 2035 No Build Alternative. By adding an exclusive left-turn lane on the northbound and southbound approaches,

the total delay at the intersection would be reduced to better than that projected for the 2035 No Build Alternative.

IP-37-64

It is important to note that the referenced intersection (Intersection ID No. 97, Ford Blvd./3rd St.) is impacted only under Alternative 7. There was no impact identified at this intersection under Alternative 5C.

With respect to Alternative 7, the analysis conducted for this location demonstrated that the intersection would benefit with the additional northbound right-turn lane, and the conceptual sketches illustrating the improvements proposed under Alternative 7 showed that there would be a partial right-of-way acquisition needed to implement this mitigation improvement. For reference, these conceptual sketches were included in the appendices to the *Intersection Traffic Impact Analysis Report* (March 2017).

IP-37-65

The row in Table 3.5-7 containing Intersection ID No. 180 (3rd St./S Gage Ave.) has been updated for consistency in this Final EIR/EIS to read “East Los Angeles (unincorp)” rather than “County.” Measure TR-1 would include improvements at this intersection, should a build alternative be selected as the Preferred Alternative.

IP-37-66

Conceptual sketches illustrating the recommended improvements proposed under Measure TR-1 showed that sliver right-of-way acquisition(s) would be necessary to implement the proposed improvements at this location, should a build alternative be selected as the Preferred Alternative. The use of these commercial properties would not be affected, as the acquisitions would not result in displacement of the property. These conceptual sketches were included as Appendix E to the *Intersection Traffic Impact Analysis Report* (March 2017). It is important to note that since the No Build Alternative has been selected as the Preferred Alternative, Measure TR-1 will not be implemented.

IP-37-67

The Community Health Benefit Program is a programmatic feature of the build alternatives. It is intended to be a project enhancement and is not a mitigation measure or intended to address the impacts of the build alternatives specifically. Many of the suggestions listed, such as greenscape projects in schools and learning centers, additional landscape and tree planting, water conservation projects, and air purifiers, may be projects eligible for funding under the Community Health Benefit Program, and the commenter is encouraged to apply for funding for these projects. However, since a build alternative has not been selected as the Preferred Alternative, this

programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway.

IP-37-68

The noise impacts of the I-710 Corridor Project were evaluated in Section 3.14, Noise, of the RDEIR/SDEIS. CEQA and NEPA only require that the RDEIR/SDEIS evaluate and abate noise impacts resulting from the build alternatives. Noise studies encompassing all of East Los Angeles are not required for a single transportation project. However, any future planned projects within East Los Angeles would be similarly required to evaluate and abate for noise impacts.

IP-37-69

Design Options 3A and 3B are no longer under consideration. Please refer to Section 1.1 of this appendix for a discussion on the identification of the Preferred Alternative.

IP-37-70

As detailed in Section 3.14, per the Caltrans Traffic Noise Analysis Protocol, reasonable (i.e., cost does not exceed total reasonable allowance) and feasible (i.e., achieving greater than a 5 dBA noise reduction) soundwalls would be constructed should a build alternative be selected as the Preferred Alternative. In addition, the I-710 Corridor Community Health Benefit Program is included as a programmatic component of the build alternatives. Should a build alternative be selected as the Preferred Alternative, the I-710 Corridor Community Health Benefit Program would take the form of a grant program structured to provide corridor communities the opportunity to implement projects or outreach activities that would improve public health related to I-710 travel and goods movement, including impacts related to noise. One of the categories of project that would be eligible and considered for funding under the program would include noise reduction measures at local schools and other sensitive receptors or related sites. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more information on the Community Health Benefit Program.

IP-37-71

This comment requests that the build alternatives be revised so that all soundwalls in East Los Angeles are constructed at maximum height to address cumulative impacts from existing, proposed, and probable future I-5 freeway, SR-60, and Gold Line expansions. Section 3.25, Cumulative Impacts, of the RDEIR/SDEIS considered a potential extension of the Gold Line along SR-60 (the Eastside Transit Corridor Phase 2 [Project T-76 in Table 3.25-1]) and a potential widening of I-5 between I-605 and I-710 in the East Los Angeles area (the I-5 Corridor

Improvement Project [Project T-5 in Table 3.25-1]). Although Section 3.25 considered potential impacts related to the SR-60 Freeway Improvement Project (Project T-18 in Table 3.25-1), which constructed high-occupancy vehicle (HOV) lanes in both directions on SR-60 between SR-57 and I-605, Caltrans has no current plans to widen SR-60 through East Los Angeles. Because State CEQA Guidelines Section 15187(d) discourages lead agencies from engaging in speculation or conjecture when conducting environmental analyses, the cumulative impacts analysis only reflects projects that have been proposed, planned, approved, or under construction.

The cumulative noise analysis included in Section 3.25.4.13, Noise, of the RDEIR/SDEIS acknowledges that some of the reasonably foreseeable transportation projects would result in increases in ambient noise levels in the long term that would not be able to be avoided or substantially mitigated. The build alternatives propose some new soundwalls, as well as increases in heights in existing soundwalls along the I-710 Corridor and would result in only a minor increase in ambient noise levels. It is also expected that many of the other cumulative transportation and land use projects in the area would also result in increases in long-term noise levels in the Resource Study Area. As noted in the Response to Comment IP-37-68, any future projects within East Los Angeles would each be similarly required to evaluate and abate noise impacts; however, some of those impacts may not be substantially or feasibly abated. Therefore, the build alternatives may contribute to long-term cumulative adverse noise impacts, specifically in the vicinity of Commerce and East Los Angeles. However, since a build alternative has not been selected as the Preferred Alternative, there will be no cumulative impact related to noise from the build alternatives.

IP-37-72

The design of soundwalls as a form of noise abatement is not intended to eliminate the entire increase in noise created by the build alternatives. Per the Caltrans Traffic Noise Analysis Protocol, a soundwall is considered for construction if it is determined to be both feasible and reasonable. A soundwall is considered to be feasible if should it reduce noise levels by a minimum of 5 dB at an impacted receptor. A soundwall is considered reasonable if it meets the acoustical design goal of a 7 dB or more reduction at one or more benefited receptor and is found to be cost-effective. The Traffic Noise Protocol goes on to specify that the Noise Abatement Criteria are not design goals for noise abatement, but rather thresholds at which noise impacts are considered to occur.

As shown in Table 2-3 of the Noise Abatement Decision Report, at this location, Alternative 5C would remove the existing wall which would increase the noise level by 12 dB compared to existing conditions, which would result in a predicted 76 dBA noise level for the 2035 design year. Should a build alternative be selected as the Preferred Alternative, SW-516 and SW-517 would be constructed at this location at a height of 16 feet to replace the existing wall, which would be removed as part of the build alternatives and would reduce noise levels at this location by up to

10 dBA at one or more benefitted receptors. However, since the No Build Alternative has been selected as the Preferred Alternative, removal of existing walls will not occur.

IP-37-73

The design of SW-518 under Design Option 3A has a different, longer on-ramp alignment that would place the top of the proposed soundwall at a higher elevation than that of SW-518 under the Alternative 5C base option. This difference in elevation caused the second row of homes to benefit and reach a reduction in noise of 5 dBA, thereby making SW-518 under the Design Option cost-reasonable. The Calvary Cemetery is the primary land use and without a formalized memorial gathering area, cemeteries are not considered a noise-sensitive land use according to the Caltrans Traffic Noise Analysis Protocol, and were not evaluated for impacts. A jogging track would be considered an “active sport area” as listed in Table 3.14-1 of Section 3.14 of the RDEIR/SDEIS, thereby falling into Activity Category C. Activity Category C also includes cemeteries. Therefore, the installation of a jogging track at Calvary Cemetery would not change the activity criteria values at this location used for impact determination.

In addition, the term benefited receptor only refers to receptors at which a 5 dBA or greater reduction in noise levels would occur and not to any nearby receptor.

IP-37-74

This comment specifically refers to Alternative 5C, Option 3A, which has been removed from consideration due, in part, to public input. No further analysis will be done on this design option.

IP-37-75

The Protocol goes on to specify that the Noise Abatement Criteria are not design goals for noise abatement, but rather are thresholds at which noise impacts are considered to occur. Additionally, the 11 dBA increase does not trigger the threshold for a substantial increase which is considered to be 12 dBA.

In regards to the wall height potentially chosen for construction, as shown in Table 2-4, because a 16-foot- high wall would provide no additional noise reduction nor would it add benefited receptors, the 14-foot- high wall was chosen for consideration to be constructed. A 22-foot-high wall was not considered in this analysis. However, since the No Build Alternative has been selected as the Preferred Alternative, soundwalls will not be constructed as part of the build alternatives.

IP-37-76

The Protocol specifies that the design of soundwalls as a form of noise abatement is not intended to eliminate the entire increase in noise created by the build alternatives and that the Noise Abatement Criteria are not design goals for noise abatement, but rather are thresholds at which noise impacts are considered to occur.

As shown in Table 3-8 of the Noise Abatement Decision Report, at this location, Alternative 7 would remove the existing walls which would increase the noise level by 13 dB compared to existing conditions, which would result in a predicted 77 dBA noise level for the 2035 design year. Should a build alternative be selected as the Preferred Alternative, SW-716 and SW-717 would be constructed at this location at a height of 16 feet to replace the existing wall, which would be removed as part of the build alternatives and would reduce noise levels at this location by up to 9 dBA at one or more benefitted receptors. However, it is important to note that a build alternative has not been identified as the Preferred Alternative and SW-716 and SW-717 will not be constructed.

IP-37-77

Please refer to Response to Comment IP-37-73 regarding provision of a soundwall at Calvary Cemetery.

IP-37-78

The commenter suggests that for SW-719 that the increase will be 10 dBA and that a 14-foot wall or 16-foot wall will reduce sound by 1 dBA. As shown in Table 2-8 of the Noise Abatement Decision Report, the reduction that would be expected at these heights would be 5 dBA.

IP-37-79

The reasonableness and feasibility of the soundwalls proposed for the build alternatives were determined in accordance with the requirements of the Caltrans Traffic Noise Analysis Protocol. The 5 dBA reduction is considered in determining if a soundwall is feasible, whereas the 7 dBA reduction is considered in determining if a soundwall is reasonable. A soundwall must be considered both feasible and reasonable in order to be constructed. As discussed in Section 3.14.5.7, Feasibility, in Section 3.14, Noise, of the RDEIR/SDEIS, per the Caltrans Traffic Noise Analysis Protocol, abatement measures are considered acoustically feasible if a minimum noise reduction of 5 dBA at impacted receiver locations is predicted with implementation of the abatement measures. Other considerations include topography, access requirements, other noise sources, and safety considerations.

As discussed in Section 3.14.5.8, Reasonableness, in Section 3.14, Noise, of the RDEIR/SDEIS, the reasonableness of a soundwall is determined by comparing the estimated cost of the

soundwall construction against the total reasonable allowance. The total reasonable allowance is determined based on the number of benefited residences multiplied by the reasonable allowance per residence. Additionally, in accordance with the Caltrans Traffic Noise Analysis Protocol, each soundwall must provide at least 7 dBA of noise reduction at one or more benefited receiver(s) to be considered reasonable.

IP-37-80

Please refer to Response to Comment IP-37-73 regarding SW-518 and SW-718.

IP-37-81

Soundwall SW-719 was not presented for further consideration because it would not meet the 7 dBA design goal, nor would it be cost effective; thus it was identified as unreasonable.

IP-37-82

All schools within the Study Area were considered for impacts, and feasible and reasonable abatement has been recommended where those impacts resulting from the build alternatives have been identified. All schools listed in this comment (with the exception of Ford Elementary and Humphreys Avenue Elementary Schools) are beyond the limits of the proposed improvements of the build alternatives (e.g., north of SR-60) or far enough from the I-710 mainline that noise impacts would not occur. Two 16-foot-high soundwalls were recommended for the build alternatives at Ford Elementary School that would provide noise reduction. The existing 12-foot-high soundwalls at Humphreys Avenue Elementary School currently provide traffic noise abatement, and increasing the height of these soundwalls would not provide a noticeable noise reduction. However, since the No Build Alternative has been selected as the Preferred Alternative, these soundwalls would not be constructed as part of the build alternatives. It should be noted that noise reduction measures at local schools and other sensitive receptors or related sites are considered eligible projects for funding under the Community Health Benefit Program, a programmatic element of the build alternatives, for which school districts would be encouraged to apply. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more information regarding the Community Health Benefit Program.

IP-37-83

Soundwall aesthetic treatments were discussed in Measures VIS-1 and VIS-4, detailed in Section 3.6.4 of the RDEIR/SDEIS. Per Measure VIS-1, the *I-710 Corridor Aesthetics Master Plan* (2014) has been developed in a context-sensitive design process in consultation with the affected local agencies and would include involvement of local community members as determined by the local

agencies, should a build alternative be selected as the Preferred Alternative. However, since the No Build Alternative has been selected as the Preferred Alternative, Measure VIS-1 will not be implemented.

IP-37-84

The proposed soundwalls for the build alternatives were designed as required in the Caltrans Protocol and Technical Noise Supplement. In order to extend a wall, an impacted receptor must be identified. If a receptor, regardless of classification, is not identified as impacted, noise abatement is not typically considered.

IP-37-85

Since the No Build Alternative has been selected as the Preferred Alternative, the programmatic parking restrictions proposed in the RDEIR/SDEIS are no longer under consideration.

IP-37-86

Caltrans and Metro welcome the comment to consider only ZE buses for the Rapid Bus Transit line through East Los Angeles included in the programmatic features for the build alternatives. Metro has already moved towards cleaner buses, which operate on recycled compressed natural gas and which reduce vehicle NO_X emissions to 90 percent lower than the current EPA limit of 0.2 grams per brake horsepower-hour. In 2017, the Metro Board adopted plans to transition to a 100 percent ZE bus fleet and issued contracts for the first phase of 95 electric buses. While Metro's fleet transition plan to ZE buses is contingent on continuous advancements in electric bus technology and a drop in vehicle prices as the technology develops, under the current proposal, the phased plan would reach its target of full zero emissions by 2030 (Metro Board Report No. 50, July 27, 2017.)

IP-37-87

This comment suggests that the cumulative impacts from the build alternatives and the Gold Line project are not fully assessed in Section 3.25 of the RDEIR/SDEIS. Please refer to Response to Comment L-31-117 regarding the cumulative impacts assessment.

IP-37-88

This comment states that cumulative noise and pollution impacts in East Los Angeles from existing, proposed, and potential future freeway projects need to be mitigated to the fullest extent possible in the RDEIR/SDEIS. Section 3.25, Cumulative, in the RDEIR/SDEIS and this Final EIR/EIS discusses a potential extension of the Gold Line along SR-60 (the Eastside Transit Corridor Phase 2 [Project T-76 in Table 3.25-1]) and a potential widening of I-5 between I-605 and I-710 in the East Los Angeles area (the I-5 Corridor Improvement Project [Project T-5 in Table

3.25-1]). As stated in Sections 3.25.4.12 and 3.25.4.13 of the RDEIR/SDEIS and this Final EIR/EIS, the I-710 Corridor Project may contribute to long-term cumulative air quality and noise impacts at receivers near the I-710 Corridor. Should a build alternative be selected as the Preferred Alternative, impacts related to air quality and noise would be mitigated to the maximum extent feasible as described in Section 3.13, Air Quality, and Section 3.14, Noise, of the RDEIR/SDEIS and this Final EIR/EIS, respectively. Although Caltrans has not currently identified any potential highway widening projects along SR-60 in East Los Angeles, Caltrans has a standing policy of evaluating proposed projects near any highway facilities to determine if they could interfere with possible future freeway projects. However, as stated in Response to Comment L-31-1, the No Build Alternative has been selected as the Preferred Alternative and therefore, there will be no cumulative impacts related to the build alternatives.

IP-37-89

Caltrans and Metro both respectfully disagree that the RDEIR/SDEIS is deficient. Based, in part, on community feedback, the No Build Alternative has been selected as the Preferred Alternative, and Design Options 3A and 3B have been withdrawn from consideration. Please refer to Section 1.8 of this appendix for more information regarding Motion 22.1 and the CA-7 Alternative, and how it was discussed in the RDEIR/SDEIS. Section 3.3.2.3, Motion 22.1 Right of Way Avoidance Analysis, in the RDEIR/SDEIS contained a discussion of the analysis undertaken to examine the potential right-of-way impacts of Alternative 7. Please refer to Section 1.7 of this appendix for more information regarding the Early Action Program. For clarity, this Early Action Program is now referred to as the “Initial Construction Stages” program.

IP-37-90

As discussed in Chapter 5 of the *Traffic Noise Study Report* (May 2016), a field investigation was conducted to identify land uses that could be subject to traffic and construction noise impacts from the build alternatives, which included schools. As stated in the Protocol, noise abatement is only considered for areas of frequent human use that would benefit from a lowered noise level. Based on the distance from the Study Area and intervening structures, Ford Elementary School, Marianna Avenue Elementary School, Alphonso B. Perez Special Education Center, Brooklyn Avenue Elementary School, Hilda L. Solis Learning Academy, Winter Garden Elementary School, Rowan Avenue Elementary School, KIIP Iluminar Academy, Morris K. Hamasaki Elementary School, and Centro Estrella would not be subject to increased construction and traffic noise from the build alternatives.

Noise impacts from the project were evaluated at the Humphreys Avenue Elementary School. There are existing 12-foot-high soundwalls along the northbound I-710 that provide noise reduction to this school. Noise abatement was considered at this location since freeway traffic noise impacts resulting from the build alternatives were predicted for this area. However, based on the noise analysis, increasing the height of the existing 12-foot-high soundwall to 16 feet would

only provide a noise level reduction of one to two dB. Therefore, a higher soundwall would not provide the minimum required noise reduction of five dB for acoustical feasibility and seven dB noise reduction to at least one receptor for reasonableness.

IP-37-91

Please refer to Response to Comment IP-37-46 regarding air quality monitoring to all sensitive receptors along I-710.

IP-37-92

Please refer to Response to Comment IP-37-83 regarding aesthetic impacts as a result of soundwalls.

IP-37-93

Please refer to Response to Comment IP-37-84 regarding provision of a soundwall at the Humphrey's Avenue Elementary School.

IP-37-94

The Community Health Benefit Program is a programmatic element of the build alternatives and has been developed beyond what was included in the RDEIR/SDEIS, and those details can be found in Section 2.3.2.1 of this Final EIR/EIS. Eligible applicants would include public and some private agencies. Individual private citizens and businesses are not considered eligible applicants. However, since a build alternative has not been selected as the Preferred Alternative, the Community Health Benefit Program would need to be implemented as part of a separate process.

IP-37-95

The projects listed, including passive greenscape projects and additional trees and landscaping, may be eligible for funding under the Community Health Benefit Program. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway.

IP-37-96

With regard to build alternatives, the Level of Service (LOS) designation on I-710 would not change in the future year (2035). In East Los Angeles, the section of I-710 between I-5 and SR-60 would operate at LOS F under the future No Build Alternative. Under the build alternatives, this segment of I-710 would remain LOS F. However, given the severity of traffic congestion throughout the metropolitan region, there are different gradients of LOS F that can be quantified

using alternative means. VISSIM traffic modeling software was utilized as an additional analysis tool to examine congestion bottlenecks in key areas along the I-710 for the p.m. peak hour in order to help inform the design of the build alternatives during project development. This VISSIM analysis shows that the auxiliary lanes included in the build alternatives would relieve the congestion bottleneck between I-5 and SR-60 to some extent. Vehicle density would be reduced and freeway speeds would still be low, but would improve by 3 mph in the southbound direction and 12 mph in the northbound direction under Alternative 5C relative to future No Build conditions in this congestion hot spot location. In addition, Tables 5-1, 5-2, 5-7, and 5-8 provided in the *I-710 Corridor Project Traffic Operations Analysis Report* (March 2017) demonstrate that levels of service on I-710 north of SR-60 would not be affected by implementation of Alternative 5C. However, as shown in Tables 5-1, 5-2, 5-10, and 5-11 provided in the *I-710 Corridor Project Traffic Operations Analysis Report* (March 2017), levels of service on I-710 north of SR-60 under Alternative 7 would be slightly worse in the northbound direction during the PM peak hour and slightly higher in the southbound direction during the AM and midday peak hours. However, as stated previously, the No Build Alternative has been selected as the Preferred Alternative and this impact under Alternative 7 would not occur.

The main purpose of the proposed project as discussed in Section 1.2 of the RDEIR/SDEIS are to address congestion, design deficiencies, traffic operations, and safety concerns on I-710 as well as related air quality issues associated with operation of the I-710 freeway as a result of the build alternatives. Over 185 local intersections were evaluated as part of this process to determine if the proposed build alternatives would result in traffic impacts to the arterial system, and if so, to identify mitigation. The number and locations of the study intersections were identified prior to the initiation of the traffic studies performed for the RDEIR/SDEIS, and were reviewed and approved by the I-710 Technical Advisory Committee. Approximately 24 of these traffic analysis intersections are located within East Los Angeles, more than any other local jurisdiction in the I-710 Study Area, with the exception of the City of Long Beach. Nearly half of the I-710 Corridor is located in the City of Long Beach.

Additionally, a component of the build alternatives targeted to addressing mobility, safety, and congestion traffic concerns on the local arterial system within the I-710 Study Area is the Congestion Relief Program, described in Section 2.3.2.1 of the RDEIR/SDEIS and this Final EIR/EIS. The program would be structured to provide the flexibility necessary to respond to local needs and issues. The program would provide funding directly to local jurisdictions, including the County of Los Angeles acting on behalf of East Los Angeles, to set priorities for congested intersections most influenced by the freeway system within the I-710 Study Area under future No Build conditions. Should a build alternative be selected as the Preferred Alternative, the County of Los Angeles, working with Metro, would play a material role in identifying the need for improvements and in developing essential, competitive projects for the area. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element

will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway.

IP-37-97

Since the No Build Alternative has been selected as the Preferred Alternative, the programmatic parking restrictions on arterials have been removed from further consideration.

IP-37-98

As discussed in Section 1.2.2 in Chapter 1.0, Proposed Project, of the RDEIR/SDEIS, one of the purposes of the project is to improve air quality and public health. The build alternatives propose Measure AQ-3 which would provide for the installation of vegetation in combination with solid barriers, where feasible, to disperse pollution and reduce pollutant concentrations downwind. Additionally, the I-710 Corridor Community Health Benefit Program is a programmatic component of the build alternatives and would take the form of a grant program structured to provide corridor communities the opportunity to implement projects or outreach activities that would improve air quality. However, since a build alternative has not been selected as the Preferred Alternative, Measure AQ-3 will not be implemented and the Community Health Benefit Program will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more information regarding the Community Health Benefit Program.

The commenter's concern regarding pavement deterioration on local streets as a result of increased traffic from the build alternatives is acknowledged and included in the project record. However, since the No Build Alternative has been selected as the Preferred Alternative, no pavement deterioration on local streets will occur as a result of the build alternatives.

IP-37-99

The commenter's opposition to Design Options 3A and 3B are acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative, and Design Option 3A is no longer under consideration.

IP-37-100

The commenter's opposition to the acquisition of land and the displacement of commercial businesses and residential housing in East Los Angeles are acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative and would not result in the displacement of any residents or businesses in East Los Angeles.

IP-37-101

The commenter's opposition to Design Options 3A and 3B is acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative, and Design Option 3A is no longer under consideration. Therefore, the parcel at 600 S. Sydney Dr. would not be acquired.

IP-37-102

Please refer to Response to Comment IP-37-101 regarding acquisition of the parcel at 600 S. Sydney Dr.

IP-37-103

Please refer to Response to Comment IP-37-101 regarding acquisition of the parcel at 600 S. Sydney Dr.

IP-37-104

The commenter's opposition to the increased truck traffic resulting in increased air quality pollution and noise, and support of zero emissions is acknowledged and included in the project record.

As discussed in Section 1.2.2 in Chapter 1.0, Proposed Project, of the RDEIR/SDEIS, the purpose of the project includes accommodating projected traffic volumes and addressing increased traffic volumes resulting from projected growth in population; and employment, and economic activities related to goods movement. As discussed in Section 3.13, Air Quality, in the RDEIR/SDEIS, all build alternatives would generally improve air quality and reduce public health risk. Along I-710, air quality would be improved and public health risk would be reduced at most locations, but there are a few near-roadway locations where there would be an increase in certain emissions. The build alternatives propose Measures AQ-2 and AQ-3 to reduce exposure to emissions at near-roadway locations. Should a build alternative be selected as the Preferred Alternative, Measure AQ-2 would provide for installation of filters on the ventilation systems of schools within 0.25 mile of I-710. Measure AQ-3 would provide for the installation of solid barriers and installation of vegetation where soundwalls are not proposed to disperse pollution and reduce pollutant concentrations downwind. In addition, the build alternatives would include programmatic components to help improve air quality and public health in the I-710 Corridor. The I-710 Corridor Community Health Benefit Program is a programmatic component of the build alternatives and would take the form of a grant program structured to provide corridor communities the opportunity to implement projects or outreach activities that would improve air quality and public health related to I-710 travel and goods movement. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer

to Section 1.10 of this appendix for more information regarding the Community Health Benefit Program.

As detailed in Section 3.14, per the Caltrans Traffic Noise Analysis Protocol, reasonable (i.e., cost does not exceed total reasonable allowance) and feasible (i.e., achieving greater than a 5 dBA noise reduction) soundwalls would be constructed as part of the build alternatives. However, since the No Build Alternative has been selected as the Preferred Alternative, no soundwalls will be constructed.

IP-37-105

Please refer to Response to Comment IP-37-14 for more information regarding Health Impact Assessments.

It should be noted that the increase in cancer risk under Alternative 5C that includes Humphreys Avenue Elementary School would be very small (an increase of one in one million), and measures to add or enhance filtration systems at the school are proposed for the build alternatives. The build alternatives propose Measures AQ-2 and AQ-3 to reduce exposure to emissions at near-roadway locations. Should a build alternative be selected as the Preferred Alternative, Measure AQ-2 would provide for installation of filters on the ventilation systems of schools within 0.25 mile of I-710, including Humphreys Avenue Elementary School and Measure AQ-3 would require installation of solid barriers and installation of vegetation where soundwalls are not proposed to disperse pollution and reduce pollutant concentrations downwind. However, since the No Build Alternative has been selected as the Preferred Alternative, Measures AQ-2 and AQ-3 will not be implemented.

IP-37-106

Should a build alternative be selected as the Preferred Alternative, Measures AQ-2 and C-8 (described in more detail in Sections 3.13.4 and 3.3.3.7, respectively) would be implemented and would require that schools within 0.25 mile of the build alternatives and sensitive receptors falling within an area of pollutant increase would receive upgraded or new filtration or HVAC systems. No other specific mitigation for the build alternatives is proposed at this time. However, should Metro or other public agencies with jurisdiction over a particular element of the Community Health Benefit Program implement the program as a part of a separate process, eligible facilities would be encouraged to apply.

IP-37-107

The commenter’s opposition to the removal of the DaVita Doctors Dialysis Center on Eastern is acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative and therefore, will not result in the displacement of the Dialysis Center

IP-37-108

The commenter's concern about effects of air quality pollution on residents living near the freeway is acknowledged and noted for the project record. As discussed in Section 1.2.2 in Chapter 1.0, Proposed Project, of the RDEIR/SDEIS, one of the purposes of the project is to improve air quality and public health. As discussed in Section 3.13, Air Quality, in the RDEIR/SDEIS, all build alternatives would generally improve air quality and reduce public health risk. Along I-710, air quality would be improved and public health risk would be reduced at most locations, but there would be a few near-roadway locations where there would be an increase in certain emissions but no increase in cancer risk compared to the 2012 Baseline.

When compared to the 2035 No Build Alternative, both build alternatives would reduce cancer risk at most locations; however, a small increase in cancer risk would occur at some locations within 100 meters of I-710. For Alternative 5C, the maximum increase in risk would be approximately three in one million. The primary location of the increased risk for Alternative 5C would occur along a small portion of I-710 just south of SR-60. For Alternative 7, the increase in risk would be less than one in one million.

The build alternatives propose Measures AQ-2 and AQ-3 to reduce emissions at near-roadway locations. Should a build alternative be selected as the Preferred Alternative, Measure AQ-2 would provide for the installation of filters on the ventilation systems of schools near I-710. Measure AQ-3 would require installation of solid barriers where soundwalls are not proposed and installation of vegetation to disperse pollution and reduce pollutant concentrations downwind. In addition, the build alternatives would include programmatic components to help improve air quality and public health in the I-710 Corridor. The I-710 Corridor Community Health Benefit Program is a programmatic component of the build alternatives and would take the form of a grant program structured to provide corridor communities the opportunity to implement projects or outreach activities that would improve air quality and public health related to I-710 travel and goods movement. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freewa. Please refer to Section 1.10 of this appendix for more information regarding the Community Health Benefit Program.

IP-37-109

Under the build alternatives, several soundwalls are proposed to be located along I-710 in East Los Angeles between SR-60 and I-5. Please refer to sheets 33 through 35 of Figure 3.14-2 in the RDEIR/SDEIS for the soundwalls proposed in East Los Angeles for Alternative 5C, and sheets 32 and 33 of Figure 3.14-3 in the RDEIR/SDEIS for the soundwalls proposed in East Los Angeles for Alternative 7. However, as stated in Response to Comment L-37-2, the No Build Alternative has been selected as the Preferred Alternative and therefore, these soundwalls will not be constructed.

IP-37-110

As stated in Response to Comment L-37-2, the No Build Alternative has been selected as the Preferred Alternative and therefore, the programmatic parking restrictions on arterials proposed as part of the build alternatives have been removed from further consideration.

IP-37-111 (comment submitted in Spanish)

The commenter's opposition to Design Options 3A and 3B are acknowledged and included in the project record. Please refer to Section 1.1 of this appendix for a discussion on the identification of the Preferred Alternative (Alternative 1 No Build).

La oposición de la comentarista a las Opciones de Diseño3A and 3B es reconocido y consignará en el documento del proyecto. Por favor, haga referencia a la Section 1.1 de este apéndice para más discusión sobre la identificación del Preferred Alternative.

IP-37-112 (comment submitted in Spanish)

The commenter's opposition to the acquisition of homes on S. Sydney Dr. in East Los Angeles is acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative and therefore, no homes on S. Sydney Dr. will be subject to relocation.

La oposición de la comentarista de la toma de viviendas en S. Sydney Dr. en East Los Angeles es reconocido y consignará en el documento del proyecto. La Alternativa 5C ha sido identificada como la Preferred Alternative. Al parte de la Preferred Alternative, ninguna casa en S. Sydney Drive estará sujeta a reubicación. La Preferred Alternative incluye una adquisición parcial de terrenos de las residencias en 656, 680, 700, 710 y 716 S. Sydney Drive; sin embargo, las adquisiciones no requerirán el desplazamiento de estas casas. Por favor, haga referencia al Appendix L, Parcel Acquisitions Under Alternatives 5C and 7, en este Final EIR / EIS, para obtener una lista completa de las adquisiciones de propiedades.

IP-37-113 (comment submitted in Spanish)

Please refer to Response to Comment IP-37-112 regarding the acquisition of homes on S. Sydney Dr.

Por favor, haga referencia al Comentario IP-37-112 en relación con la adquisición de viviendas en S. Sydney Dr.

IP-37-114 (comment submitted in Spanish)

Please refer to Response to Comment IP-37-112 regarding the acquisition of homes on S. Sydney Dr.

Por favor, haga referencia al Comentario IP-37-112 en relación con la adquisición de viviendas en S. Sydney Dr

IP-37-115 (comment submitted in Spanish)

As stated in Response to Comment L-37-2, the No Build Alternative has been selected as the Preferred Alternative and therefore, the programmatic parking restrictions on arterials proposed as part of the build alternatives have been removed from further consideration.

Como se indicó en la respuesta al comentario L-37-2, la alternativa de no construir ha sido seleccionada como la alternativa preferida y, por lo tanto, las restricciones programáticas de estacionamiento en las arterias propuestas como parte de las alternativas de construir han sido eliminadas de consideración.

IP-37-116 (comment submitted in Spanish)

The commenter's opposition to Design Options 3A and 3B are acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative and Design Options 3A and 3B are no longer under consideration.

La oposición del comentador a las Opciones de Diseño 3A y 3B son reconocidas e incluidas en el expediente del proyecto. La Alternativa 1 (No Construir) ha sido identificada como la Alternativa Preferida y las Opciones de Diseño 3A y 3B ya no están bajo consideración..

IP-37-117 (comment submitted in Spanish)

The commenter's opposition to increasing truck traffic on I-710 is acknowledged and included in the project record. As discussed in Section 3.14, Air Quality, the build alternatives would increase PM_{10} emissions in the vicinity of I-710 from increases in entrained road dust, tire wear and brake wear (which are a direct function of vehicle miles traveled) compared to the 2012 Baseline and the 2035 No Build Alternative.

La oposición del autor del comentario al aumento del tráfico de camiones en la I 710 se reconoce y se incluye en el expediente del proyecto. Como se discutió en la Sección 3.14, Calidad del Aire, las alternativas de construcción aumentarían las emisiones de PM10 en las inmediaciones de la I 710 por el aumento de polvo arrastrado por la carretera, el desgaste de los neumáticos y el desgaste de los frenos (que son una función directa de las millas recorridas por los vehículos) en comparación con la línea de base de 2012 y la alternativa de no construir en 2035.

IP-37-118 (comment submitted in Spanish)

Please refer to Response to Comment IP-37-14 for more information regarding Health Impact Assessments.

Schools (from kindergarten through 12th grade) are considered sensitive receptors under the Caltrans Traffic Noise Analysis Protocol and were taken into consideration in the noise analysis.

It should be noted that the increase in cancer risk under Alternative 5C that includes Humphreys Avenue Elementary School would be very small (an increase of one in one million), and measures to add or enhance filtration systems at the school are proposed for the build alternatives. Should a build alternative be selected as the Preferred Alternative, Measures AQ-2 and AQ-3 would reduce exposure to emissions at near-roadway locations. Measure AQ-2 would provide for installation of filters on the ventilation systems of schools within 0.25 mile of I-710, including Humphreys Avenue Elementary School. Measure AQ-3 would provide for the installation of solid barriers and installation of vegetation where soundwalls are not proposed to disperse pollution and reduce pollutant concentrations downwind. However, since the No Build Alternative has been selected as the Preferred Alternative, Measures AQ-2 and AQ-3 will not be implemented.

Consulte la respuesta al comentario IP-37-14 para obtener más información sobre las evaluaciones del impacto sobre la salud.

Las escuelas (desde el jardín de infancia hasta el 12º grado) se consideran receptores sensibles según el Protocolo de análisis del ruido del tráfico de Caltrans y se tuvieron en cuenta en el análisis del ruido.

Cabe señalar que el aumento del riesgo de cáncer en la alternativa 5C que incluye la escuela primaria Humphreys Avenue sería muy pequeño (un aumento de uno en un millón), y se proponen medidas para añadir o mejorar los sistemas de filtración en la escuela para las alternativas de construcción. En caso de que se elija una alternativa de construcción como alternativa preferida, las medidas AQ-2 y AQ-3 reducirían la exposición a las emisiones en lugares cercanos a la carretera. La medida AQ-2 dispondría la instalación de filtros en los sistemas de ventilación de las escuelas situadas a 0,25 millas de la I 710, incluida la Escuela Primaria Humphreys Avenue. La medida AQ-3 dispondría la instalación de barreras sólidas y la instalación de vegetación donde no se propongan pantallas acústicas para dispersar la contaminación y reducir las concentraciones de contaminantes a sotavento. Sin embargo, dado

que la alternativa de no construir ha sido seleccionada como la alternativa preferida, las medidas AQ-2 y AQ-3 no se implementarán.

IP-37-119 (comment submitted in Spanish)

Noise increases in East Los Angeles were modeled at Receptors NB-46 through NB-55. As shown in Table 3.12-2 in Section 3.14, Noise, of the RDEIR/SDEIS, the change in noise levels at these receptors would range from -1.4 dBA to 12.6 dBA for Alternative 5C and from -1.1 dBA to 12.9 dBA for Alternative 7. Soundwalls were considered at all impacted receptors to reduce noise impacts resulting from the build alternatives. As detailed in Section 3.14, per the Caltrans Traffic Noise Analysis Protocol, reasonable (i.e., wherein the cost does not exceed total reasonable allowance) and feasible (i.e., achieving greater than a 5 dBA noise reduction) soundwalls would be constructed should a build alternative be selected as the Preferred Alternative. Soundwalls determined to be feasible and reasonable were outlined in Section 3.14.5.10, Preliminary Decision on Soundwalls, of the RDEIR/SDEIS. However, since the No Build Alternative was selected as the Preferred Alternative, no soundwalls will be constructed.

Los aumentos de ruido en el este de Los Ángeles se modelaron en los receptores NB-46 a NB-55. Como se muestra en la Tabla 3.12-2 de la Sección 3.14, Ruido, del RDEIR/SDEIS, el cambio en los niveles de ruido en estos receptores oscilaría entre -1,4 dBA y 12,6 dBA para la Alternativa 5C y entre -1,1 dBA y 12,9 dBA para la Alternativa 7. Se consideraron muros de contención acústica en todos los receptores afectados para reducir el impacto acústico resultante de las alternativas de construcción. Se estudió la posibilidad de instalar pantallas acústicas en todos los receptores afectados para reducir el impacto acústico resultante de las alternativas de construcción. Como se detalla en la sección 3.14, según el protocolo de análisis del ruido del tráfico de Caltrans, se construirían pantallas acústicas razonables (es decir, cuyo coste no supere la asignación total razonable) y viables (es decir, que logren una reducción del ruido superior a 5 dBA) si se selecciona una alternativa de construcción como alternativa preferida. En la sección 3.14.5.10, Decisión preliminar sobre muros de contención acústica, de la RDEIR/SDEIS, se describen los muros de contención acústica considerados viables y razonables. Sin embargo, dado que se seleccionó la alternativa de no construir como alternativa preferida, no se construirán muros de contención acústica.

IP-37-120 (comment submitted in Spanish)

Should a build alternative be selected as the Preferred Alternative, several soundwalls along I-710 in East Los Angeles between SR-60 and I-5 would likely be constructed. Please refer to sheets 33 through 35 of Figure 3.14-2 in the RDEIR/SDEIS for the soundwalls proposed in East Los Angeles for Alternative 5C and sheets 32 and 33 of Figure 3.14-3 in the RDEIR/SDEIS for the soundwalls proposed in East Los Angeles for Alternative 7. However, since the No Build Alternative was selected as the Preferred Alternative, no soundwalls will be constructed.

Si se selecciona una alternativa de construcción como la Alternativa Preferida, es probable que se construyan varios muros de contención acústica a lo largo de la I 710 en el Este de Los Ángeles entre la SR-60 y la I 5. Consulte las hojas 33 a 35 de la Figura 3.14-2 en el RDEIR/SDEIS para conocer los muros de contención acústica propuestos en el este de Los Ángeles para la Alternativa 5C y las hojas 32 y 33 de la Figura 3.14-3 en el RDEIR/SDEIS para conocer los muros de contención acústica propuestos en el este de Los Ángeles para la Alternativa 7. Sin embargo, dado que se eligió la alternativa de no construir como alternativa preferida, no se construirán muros de contención acústica.

IP-37-121 (comment submitted in Spanish)

As described in more detail in Section 3.14, Noise, of the Final EIR/EIS, soundwalls are proposed where feasible and reasonable throughout the I-710 Corridor to abate freeway noise impacts as a result of the build alternatives. Section 3.13 of the Final EIR/EIS, Air Quality, describes air quality-related impacts and proposed avoidance, minimization, and/or mitigation measures for the build alternatives. Further, Section 3.3.3 of the Final EIR/EIS outlines proposed mitigation measures for disproportionate adverse impacts to environmental justice communities resulting from the build alternatives, which include noise abatement and air filtration systems in specific areas. The locations of abatement or filtration systems was determined by whether or not they would fall into an area of increased noise or increased pollutants as a result of the build alternatives. However, since the No Build Alternative was selected as the Preferred Alternative, no soundwalls will be constructed and mitigation measures related to air quality will not be implemented.

Como se describe con más detalle en la Sección 3.14, Ruido, del EIR/EIS Final, se proponen muros de sonido donde sea factible y razonable a lo largo del Corredor I 710 para disminuir los impactos del ruido de la autopista como resultado de las alternativas de construcción. La Sección 3.13 del EIR/EIS Final, Calidad del Aire, describe los impactos relacionados con la calidad del aire y las medidas propuestas para evitar, minimizar y/o mitigar las alternativas de construcción. Además, la Sección 3.3.3 del EIR/EIS Final describe las medidas de mitigación propuestas para los impactos adversos desproporcionados a las comunidades de justicia ambiental resultantes de las alternativas de construcción, que incluyen la reducción del ruido y sistemas de filtración de aire en áreas específicas. La ubicación de los sistemas de reducción o filtración se determinó en función de si se encontrarían o no en una zona de aumento de ruido o de aumento de contaminantes como consecuencia de las alternativas de construcción. Sin embargo, dado que la alternativa preferida es la de no construir, no se construirán pantallas acústicas ni se aplicarán medidas de mitigación relacionadas con la calidad del aire.

IP-37-122 (comment submitted in Spanish)

The commenter's opposition to the removal of the DaVita Doctors Dialysis Center on Eastern is acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative and therefore, the DaVita Doctors Dialysis Center will not be displaced.

Se reconoce e incluye en el expediente del proyecto la oposición del comentador a la eliminación del Centro de Diálisis DaVita Doctors en Eastern. La Alternativa 1 (No Construir) ha sido identificada como la Alternativa Preferida y, por lo tanto, el Centro de Diálisis DaVita Doctors no será desplazado.

IP-37-123 (comment submitted in Spanish)

The commenter's concern about effects of air quality pollution on residents living near the freeway is acknowledged and included in the project record. As discussed in Section 1.2.2 in Chapter 1.0, Proposed Project, of the RDEIR/SDEIS, one of the purposes of the project is to improve air quality and public health. As discussed in Section 3.13, Air Quality, in the RDEIR/SDEIS, all build alternatives would generally improve air quality and reduce public health risk. Along I-710, air quality would be improved and public health risk would be reduced at most locations, but there would be a few near-roadway locations where there would be an increase in certain emissions, but no increase in cancer risk when compared to the 2012 Baseline.

When compared to the 2035 No Build Alternative, both build alternatives would reduce cancer risk at most locations; however, a small increase in cancer risk would occur at some locations within 100 meters of I-710. For Alternative 5C, the maximum increase in risk would be approximately three in one million. The primary location of the increased risk for Alternative 5C would occur along a small portion of I-710 just south of SR-60. For Alternative 7, the increase in risk would be less than one in one million.

Should a build alternative be selected as the Preferred Alternative, Measures AQ-2 and AQ-3 would reduce emissions at near-roadway locations. Measure AQ-2 would require filters on the ventilation systems of schools near I-710. Measure AQ-3 would require installation of solid barriers where soundwalls are not proposed and installation of vegetation to disperse pollution and reduce pollutant concentrations downwind. In addition, the build alternatives include programmatic components to help improve air quality and public health in the I-710 Corridor. The I-710 Corridor Community Health Benefit Program is a programmatic component of the build alternatives and would take the form of a grant program structured to provide corridor communities the opportunity to implement projects or outreach activities that would improve air quality and public health related to I-710 travel and goods movement. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the

owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more details regarding the Community Health Benefit Program.

La preocupación del autor del comentario sobre los efectos de la contaminación de la calidad del aire en los residentes que viven cerca de la autopista se reconoce y se incluye en el expediente del proyecto. Como se discute en la Sección 1.2.2 en el Capítulo 1.0, Proyecto Propuesto, del RDEIR/SDEIS, uno de los propósitos del proyecto es mejorar la calidad del aire y la salud pública. Como se discute en la Sección 3.13, Calidad del Aire, en el RDEIR/SDEIS, todas las alternativas de construcción mejorarían en general la calidad del aire y reducirían el riesgo para la salud pública. A lo largo de la I 710, la calidad del aire mejoraría y el riesgo para la salud pública se reduciría en la mayoría de los lugares, pero habría unos pocos lugares cerca de la carretera donde habría un aumento de ciertas emisiones, pero no un aumento en el riesgo de cáncer en comparación con la línea de base de 2012.

En comparación con la alternativa de no construir en 2035, ambas alternativas de construcción reducirían el riesgo de cáncer en la mayoría de las ubicaciones; sin embargo, se produciría un pequeño aumento del riesgo de cáncer en algunas ubicaciones dentro de los 100 metros de la I 710. Para la alternativa 5C, el aumento máximo del riesgo sería de aproximadamente tres en un millón. En comparación con la alternativa de no construir en 2035, ambas alternativas de construcción reducirían el riesgo de cáncer en la mayoría de los lugares; sin embargo, se produciría un pequeño aumento del riesgo de cáncer en algunos lugares dentro de los 100 metros de la I 710. Para la alternativa 5C, el aumento máximo del riesgo sería de aproximadamente tres en un millón. La ubicación principal del aumento del riesgo para la alternativa 5C ocurriría a lo largo de una pequeña porción de la I 710 justo al sur de la SR-60. En el caso de la variante 7, el aumento del riesgo sería inferior a uno entre un millón. Para la variante 7, el aumento del riesgo sería inferior a uno en un millón.

En caso de que se elija la alternativa de construcción como alternativa preferida, las medidas AQ-2 y AQ-3 reducirían las emisiones en las proximidades de las carreteras. La medida AQ-2 requeriría filtros en los sistemas de ventilación de las escuelas cercanas a la I 710. La medida AQ-3 exigiría la instalación de barreras sólidas donde no se propongan pantallas acústicas y la instalación de vegetación para dispersar la contaminación y reducir las concentraciones de contaminantes a sotavento. Además, las alternativas de construcción incluyen componentes programáticos para ayudar a mejorar la calidad del aire y la salud pública en el corredor de la I 710. El Programa de Beneficios para la Salud de la Comunidad del Corredor I 710 es un componente programático de las alternativas de construcción y tomaría la forma de un programa de subvenciones estructurado para proporcionar a las comunidades del corredor la oportunidad de implementar proyectos o actividades de divulgación que mejorarían la calidad del aire y la salud pública relacionadas con los viajes y el movimiento de mercancías en la I 710. Sin embargo, dado que no se ha seleccionado una alternativa de construcción como Alternativa Preferida, este elemento programático no será implementado por Caltrans como agencia líder bajo CEQA y

NEPA y como propietario/operador de la autopista I-710. Consulte la Sección 1.10 de este apéndice para obtener más detalles sobre el Programa Comunitario de Beneficios para la Salud.

IP-37-129

The commenter's opposition to Design Options 3A and 3B are acknowledged and included in the project record. Please refer to Section 1.1 of this appendix for a discussion on the identification of the Preferred Alternative (Alternative 1 No Build).

IP-37-130

The commenter's opposition to the taking of homes on S. Sydney Dr. in East Los Angeles is acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative. As part of the Preferred Alternative, no homes on S. Sydney Dr. will be subject to relocation.

IP-37-131

Please refer to Response to Comment IP-37-130 regarding the acquisition of homes on S. Sydney Dr. in East Los Angeles.

IP-37-132

Please refer to Response to Comment IP-37-130 regarding the acquisition of homes on S. Sydney Dr. in East Los Angeles.

IP-37-133

As stated in Response to Comment L-37-2, the No Build Alternative has been selected as the Preferred Alternative and therefore, the programmatic parking restrictions on arterials proposed as part of the build alternatives have been removed from further consideration.

IP-37-134

Please refer to Response to Comment IP-37-129 regarding Design Options 3A and 3B.

IP-37-135

The commenter's opposition to increasing truck traffic on I-710 is acknowledged and included in the project record. As discussed in Section 3.14, Air Quality, the build alternatives would increase PM_{10} emissions in the vicinity of I-710 from increases in entrained road dust, tire wear and brake wear (which are a direct function of vehicle miles traveled) compared to 2012 Baseline and compared to the 2035 No Build Alternative.

IP-37-136

Please refer to Response to Comment IP-37-14 for more information regarding Health Impact Assessments.

Schools (from kindergarten through 12th grade) are considered sensitive receptors under the Caltrans Traffic Noise Analysis Protocol and were taken into consideration in the noise analysis. It should be noted that the increase in cancer risk under Alternative 5C that would include Humphreys Avenue Elementary School would be very small (an increase of one in one million), and, should a build alternative be selected as the Preferred Alternative, measures to add or enhance filtration systems at the school would be implemented. The build alternatives propose Measures AQ-2 and AQ-3 to reduce exposure to emissions at near-roadway locations. Should a build alternative be selected as the Preferred Alternative, Measure AQ-2 would provide for installation of filters on the ventilation systems of schools within 0.25 mile of I-710, including Humphreys Avenue Elementary School. Measure AQ-3 would require installation of solid barriers and installation of vegetation where soundwalls are not proposed to disperse pollution and reduce pollutant concentrations downwind. However, since the No Build Alternative was selected as the Preferred Alternative, Measures AQ-2 and AQ-3 will not be implemented.

IP-37-137

Noise increases in East Los Angeles were modeled at Receptors NB-46 through NB-55. As shown in Table 3.12-2 in Section 3.14, Noise, of the RDEIR/SDEIS, the change in noise levels at these receptors would range from -1.4 dBA to 12.6 dBA for Alternative 5C and from -1.1 dBA to 12.9 dBA for Alternative 7. Soundwalls were considered at all impacted receptors to reduce noise impacts resulting from the build alternatives. As detailed in Section 3.14, per the Caltrans Traffic Noise Analysis Protocol, should a build alternative be selected as the Preferred Alternative, reasonable (i.e., wherein the cost does not exceed total reasonable allowance) and feasible (i.e., achieving greater than a 5 dBA noise reduction) soundwalls would be constructed. Soundwalls determined to be feasible and reasonable are outlined in Section 3.14.5.10, Preliminary Decision on Soundwalls, of the RDEIR/SDEIS. However, since the No Build Alternative was selected as the Preferred Alternative, soundwalls will not be constructed as part of the build alternatives.

IP-37-138

The build alternatives propose several soundwalls along I-710 in East Los Angeles between SR-60 and I-5. Please refer to sheets 33 through 35 of Figure 3.14-2 in the RDEIR/SDEIS for the soundwalls proposed in East Los Angeles for Alternative 5C and sheets 32 and 33 of Figure 3.14-3 in the RDEIR/SDEIS for the soundwalls proposed in East Los Angeles for Alternative 7. However, since the No Build Alternative was selected as the Preferred Alternative, these soundwalls will not be constructed as part of the build alternatives.

IP-37-139

As described in more detail in Section 3.14, Noise, of the Final EIR/EIS, soundwalls are proposed where feasible and reasonable throughout the I-710 Corridor to abate freeway noise impacts as a result of the build alternatives. Section 3.13 of this Final EIR/EIS, Air Quality, describes air quality-related impacts and proposed avoidance, minimization, and/or mitigation measures for the build alternatives. Further, Section 3.3.3 of this Final EIR/EIS outlines proposed mitigation measures for disproportionate adverse impacts to environmental justice communities resulting from the build alternatives, which would include noise abatement and air filtration systems in specific areas. The locations of abatement or filtration systems was determined by whether or not they would fall into an area of increased noise or increased pollutants as a result of the build alternatives. However, since the No Build Alternative was selected as the Preferred Alternative, these noise and air quality mitigation measures will not be implemented.

IP-37-140

The commenter's opposition to the removal of the DaVita Doctors Dialysis Center on Eastern is acknowledged and included in the project record. Alternative 1 (No Build) has been identified as the Preferred Alternative. Under the Preferred Alternative, the DaVita Doctors Dialysis Center will not be displaced.

IP-37-141

The commenter's concern about effects of air quality pollution on residents living near the freeway is acknowledged and included in the project record. As discussed in Section 1.2.2 in Chapter 1.0, Proposed Project, of the RDEIR/SDEIS, one of the purposes of the project is to improve air quality and public health. As discussed in Section 3.13, Air Quality, in the RDEIR/SDEIS, all build alternatives would generally improve air quality and reduce public health risk. Along I-710, air quality would be improved and public health risk would be reduced at most locations, but there would be a few near-roadway locations where there would be an increase in certain emissions, but no increase in cancer risk when compared to the 2012 Baseline.

When compared to the 2035 No Build Alternative, both build alternatives would reduce cancer risk at most locations; however, a small increase in cancer risk would occur at some locations within 100 meters of I-710. For Alternative 5C, the maximum increase in risk would be approximately three in one million. The primary location of the increased risk for Alternative 5C would occur along a small portion of I-710 just south of SR-60. For Alternative 7, the increase in risk would be less than one in one million.

Should a build alternative be selected as the Preferred Alternative, Measures AQ-2 and AQ-3 would be implemented to reduce emissions at near-roadway locations. Measure AQ-2 would require filters on the ventilation systems of schools near I-710. Measure AQ-3 would require

installation of solid barriers where soundwalls are not proposed to reduce noise impacts and installation of vegetation to disperse pollution and reduce pollutant concentrations downwind. In addition, the build alternatives would include programmatic components to help improve air quality and public health in the I-710 Corridor. The I-710 Corridor Community Health Benefit Program is a programmatic component of the build alternatives and would take the form of a grant program structured to provide corridor communities the opportunity to implement projects or outreach activities that would improve air quality and public health related to I-710 travel and goods movement. However, since a build alternative has not been selected as the Preferred Alternative, this programmatic element will not be implemented by Caltrans as the lead agency under CEQA and NEPA and as the owner/operator of the I-710 freeway. Please refer to Section 1.10 of this appendix for more information on the Community Health Benefit Program.

IP-37-182

The comments provided herein were made on the SR-710 North Project Draft EIR/EIS, which was released for public circulation in 2015. The SR-710 North Project is a separate SR-710 project distinct from that of the I-710 Corridor Project, which terminates at SR-60, over two miles south of the SR-710 North Project southern terminus. These comments will be responded to in the Final EIR/EIS for the SR-710 North Project.

IP-37-183

Please refer to Response to Comment IP-37-25 regarding acquisitions in East Los Angeles.

IP-37-184

As stated in Response to Comment IP-37-2, the programmatic parking restrictions on arterials proposed as part of the build alternatives have been removed from further consideration.

IP-37-185

Please refer to Response to Comment IP-37-184 regarding parking restrictions on arterials.

IP-37-186

Please refer to Section 1.2 of this appendix regarding the extension of the public comment period.

IP-37-187

Please refer to Section 1.2 of this appendix for more information regarding the public hearings held for the project. In general, Commerce was selected as the location of the public hearing for the northern end of the Study Area because of the greater amount of relocation impacts that would occur within the City as a result of the build alternatives.

IP-37-188

The commenter's opposition to all build alternatives and concern for displacement of residents and businesses in East Los Angeles as a result of the build alternatives are acknowledged and included in the project record. Caltrans and Metro determined there was a need for the build alternatives to improve air quality, address freeway capacity and transportation demands, and improve traffic safety. Please refer to Section 1.2, Need and Purpose, of this Final EIR/EIS for more details regarding the need for the project. Alternative 1 (No Build) has been identified as the Preferred Alternative and would not result in the displacement of residents or business in East Los Angeles. However, Appendix L, Parcel Acquisitions Under Alternatives 5C and 7, in this Final EIR/EIS, contains a list of full or partial acquisitions and the relative displacement for each build alternative. However, since the No Build Alternative has been selected as the Preferred Alternative, no full or partial acquisitions will be necessary.

IP-37-189

As stated in Response to Comment IP-37-2, the programmatic parking restrictions on arterials proposed as part of the build alternatives have been removed from further consideration.

IP-37-190

The motion to consider a Design Option within the East Los Angeles area was made by the County representative at the Project Committee meeting in July 2014, and the East Los Angeles LAC was briefed on the Design Options prior to performing the analysis that informed the RDEIR/SDEIS in April 2015.

Re: Union Pacific Railroad Company's Comments to the Recirculated Draft Environmental Impact Report/Supplemental Draft Environmental Impact Statement (RDEIR/SDEIS) For the Interstate 710 (710) Corridor Project

Dear Mr. Kosinski:

Union Pacific Railroad Company ("UP") appreciates this opportunity to comment on the July 2017 Recirculated Draft Environmental Impact Report/Supplemental Draft Environmental Impact Statement ("RDEIR/SDEIS") for the Interstate 710 ("710") Corridor Project ("710 Project" or "Project"), prepared by the California Department of Transportation ("Caltrans").[1]

UP has a specific interest in the proposed Project because construction and implementation of the Project will significantly impact UP rail infrastructure and operations throughout the 710 Corridor. Such impacts include permanent encroachments and construction easements upon UP's right-of-way and other operating property resulting in the loss of existing rail lines and infrastructure. The loss of rail infrastructure and land will impact the design and functioning of existing rail facilities, disrupt rail operations, and ultimately negatively affect UP's service to its customers. Given the Project impacts on UP, Caltrans must obtain a Memorandum of Understanding and Construction and Maintenance ("C&M") Agreements with UP prior to any construction within or above any railroad right-of-way.[2] IP-38-1

UP previously commented on an earlier version of the Project analyzed in a 2012 Draft EIR/EIS. UP appreciates Caltrans' desire for modernization of the existing 710 Corridor and is supportive of the proposed Project as a whole. However, the RDEIR/SDEIS introduces considerable changes to the proposed Project and a large number of new and potentially substantial impacts to UP's rail lines and operations as compared to the former 2012 plan. As a result, for reasons discussed more fully below, UP opposes the two Build Alternatives (Alternative 5C and Alternative 7) identified in the RDEIR/SDEIS to the extent that they impact IP-38-2

[1] Caltrans, in cooperation with the Los Angeles County Metropolitan Transportation Authority, the Gateway Cities Council of Governments, the Southern California Association of Governments, the Ports of Los Angeles and Long Beach, and the Interstate 5 Joint Powers Authority, are proposing to improve Interstate 710 in Los Angeles County between Ocean Blvd. and State Route 60. Caltrans is the lead agency under the National Environmental Policy Act ("NEPA") and the California Environmental Quality Act ("CEQA").
[2] These necessary approvals are acknowledged on page 2-96 of the RSEIR/SDEIS.

or potentially impact UP rail infrastructure and operations, absent reaching agreement with Caltrans regarding the full scope of potential impacts to UP's rail infrastructure and operations, implementation of feasible mitigations, and adequate compensatory solutions to address non-mitigatable Project impacts. To this end, UP requests that Caltrans initiate substantive discussions with UP's project, engineering, real estate, and legal teams prior to preparation of the Final EIR/EIS. UP also requests that Caltrans explicitly recognize and acknowledge that the Project will adhere to UP's operational and rail standards (specific to grade separation, design, health and safety, public crossing, operating standards, etc.), as applicable. IP-38-2 IP-38-3

I. UP Owns and Operates Critical Rail Lines and Rail Facilities within the Project Area, Many of Which Will be Significantly Affected by the Proposed Project

A. General

UP owns and operates a common carrier railroad network in the western half of the United States, including the State of California. Specifically, UP owns and operates main rail lines connecting San Francisco and Sacramento and points east and north, and to Los Angeles and points east and southeast. UP is the largest rail carrier in California in terms of both mileage and train operations. UP's rail network is vital to the economic health of California and the nation as a whole and its rail service to customers in the Los Angeles and 710 Corridor Area is crucial to the future success and growth of its customers.

The Ports of Los Angeles and Long Beach are the gate of entry for approximately forty percent of the goods imported into the United States, a significant portion of which are carried by rail across the Los Angeles Basin to the rest of the country. Some 1.6 million jobs in Southern California depend on the movement of these goods and UP's rail network in the Basin is a key engine of this critical component of the State's economy.

Unlike road infrastructure, railroads are fixed systems that cannot easily accommodate detours or obstructions. Each component of the rail network is critical to the overall fluidity and velocity of rail operations, and disruptions in one location can cause a cascading series of delays that can impact operations and communities, including those many miles away. For these reasons, UP is especially concerned that the proposed Project Description, as it relates to construction activities that could affect UP's rail and railyard operations, is not sufficiently detailed to allow such indirect impacts to be identified. For example, construction planned for the overpass traversing the UP East Los Angeles/Commerce Intermodal Railyard ("East LA Railyard") could cause significant disruptions in yard operations, which could affect not only the residents of Commerce, but those in communities many miles away, from the neighborhoods in Carson to those in Colton. Any limitation of the environmental evaluation of rail construction impacts that does not take into account such potential impacts is inadequate. IP-38-4

B. East LA Intermodal Railyard

Although rail disruptions anywhere on UP's lines could have significant impacts, UP's East LA Railyard is an especially important component of the UP rail network that appears particularly impacted by the proposed Project. This yard is approximately four miles southeast of downtown Los Angeles and runs directly parallel (for about a mile) and across Washington Boulevard from the largest intermodal railyard in the United States, BNSF Railway Hobart

Railyard. The UP East LA Railyard covers a triangular area surrounded by both residential and commercial properties, as well as several major freeways. An overpass for the 710 freeway bisects the East LA Railyard. To the south side of the railyard (on both sides of the 710 overpass), residences are located between the railyard fence line and Washington Boulevard. Bandini Elementary School is also located in this area. The north side of the UP East LA Railyard is surrounded by commercial properties and residential housing. Residential properties are located north of the railyard on both sides of the 710 freeway overpass, approximately 200 feet from the railyard.

Facilities within the East LA Railyard include: classification tracks, a gate complex for inbound and outbound intermodal truck traffic, intermodal loading and unloading tracks, a locomotive service track, a locomotive maintenance shop, a freight car repair shop, an on-site wastewater treatment plant, and various buildings and facilities supporting railroad and contractor operations.

The East LA Railyard is a cargo handling facility with a focus on domestic containers. An estimated 450,000 containers are processed each year. Cargo containers and other freight are received, sorted, and distributed from the facility. Intermodal containers may arrive at the facility by truck to be loaded onto trains for transport to distant destinations, or arrive by train and unloaded onto chassis for transport by truck to local destinations. Cargo containers and chassis are also temporarily stored at the railyard. The railyard also includes facilities for crane and yard hostler maintenance, locomotive service and repair, and on-site wastewater treatment.

Activities at the UP East LA Railyard include receiving inbound trains, switching rail cars, loading and unloading intermodal trains, storing intermodal containers and truck chassis, building and departing outbound trains, and repairing freight cars and intermodal containers/chassis. The railyard includes a bypassing main line with freight and passenger train traffic that is not part of the railyard operations.

Within the East LA Railyard, the primary locomotive operations are associated with arriving, departing, and servicing interstate line haul locomotives. Arriving and departing line haul locomotives are fueled in the locomotive service area after arrival, and are sent back into the railyard or to other railyards after service. A locomotive maintenance shop also performs periodic and unscheduled maintenance on locomotives. Three switch locomotives (i.e., dedicated to moving rail cars within the railyard) also operate within the railyard— one on the west end of the railyard, and a pair on the east end of the railyard. They are used to move sections of inbound trains to appropriate areas within the railyard (e.g., intermodal rail cars go to the intermodal ramp for unloading and loading), and to move sections of outbound trains to tracks from which they will depart.

In order for UP to remain a presence in the intermodal business, we modernize facilities based on present and future demands. This proposed Project needs to ensure that those future needs can be met. Any disruption of these operations can slow the processing of containers, which can result in increased truck queuing time and congestion on area streets, increased idling emissions for trucks and locomotives, intensified use of alternative routes with increased noise and emission impacts and increased congestion along the alternative routes, among other things.

The complexity of these critical operations and the impact of the Project upon them must be thoroughly analyzed in order to properly identify the Project's impacts and develop appropriate mitigation measures. IP-38-5

II. Preemption: Railroad Operations are Under the Exclusive Jurisdiction of the Federal Surface Transportation Board

Federal law recognizes the critical nature of rail operations and the needs for consistent, predictable operating conditions. Accordingly, only the Federal Surface Transportation Board ("STB") has authority to regulate the use of railroad property. As set forth in the Interstate Commerce Commission Termination Act ("ICCTA"), the STB has exclusive and preemptive jurisdiction over:

(1) transportation by rail carriers, and the remedies provided in this part with respect to rates, classifications, rules (including car service, interchange, and other operating rules), practices, routes, services, and facilities of such carriers; and

(2) the construction, acquisition, operation, abandonment, or discontinuance of spur, industrial, team, switching, or side tracks, or facilities, even if the tracks are located, or intended to be located, entirely in one State, is exclusive. Except as otherwise provided in this part, the remedies provided under this part with respect to regulation of rail transportation are exclusive and preempt the remedies provided under Federal or State law. 49 U.S.C. § 10501(b) (emphasis added).

Thus, UP's continued operation of its rail lines cannot be disturbed except as directed by the STB. Accordingly, the RDEIR/SDEIS should not assume that any (even potentially temporary) encroachment of railroad right-of-way and/or relocation or acquisition of UP's rail lines as a result of the proposed Project is feasible, and such encroachment or relocation must be thoroughly described in order to evaluate not only its impacts, but whether such requirements are preempted. IP-38-6

III. The RDEIR/SDEIS Fails to Provide Necessary Information Required for Informed Decision-Making under NEPA

As noted above, the RDEIR/SDEIS does not adequately contain sufficient detail to allow the public to understand the relevant environmental consequences of the proposed Project as related to UP rail infrastructure and operations. For the reasons set forth below, the analysis of the project is insufficient under NEPA, thereby undermining reasoned judgment on the project and failing the required purposes of such environmental and information-gathering statutes. *See Robertson v. Methow Valley Citizens Council*, 490 U.S. 332, 349 (1989) (noting NEPA's purposes are to ensure the agency will have detailed information on significant environmental impacts when it makes its decisions and to guarantee that this information will be available to a larger audience); 40 C.F.R. §§ 1502.1, 1502.14.

A. The RDEIR/SDEIS does not contain sufficient detail about potential environmental impacts of the proposed Project on rail infrastructure and operations.

NEPA requires agencies to take a good faith "hard look" at the potential consequences of a project, analyze its potential impact on the environment and identify unavoidable adverse consequences of the proposed action and of alternative actions. *See* 42 U.S.C. § 4332(C). In addition, NEPA requires agencies to consider all substantial evidence when analyzing significant impacts and consider impacts within the setting in which they occur. *See* 40 CFR § 1508.27(a)).

Here, the RDEIR/SDEIS is insufficient because it does not include a sufficiently detailed analysis of the Project's potential impacts on existing UP rail lines and operations. Instead, the environmental analysis of the two build project alternatives focuses on basic design components and the RDEIR/SDEIS includes only a mere single half page of general descriptions regarding proposed modifications to rail facilities.[3] Appendix O (Concept Plans) provides more detailed mapping showing the design features of the revised build alternatives and the locations of those features, but it is not clear from those maps whether and/or to what extent rail is impacted (see discussion in Section IV below). IP-38-7

B. <u>The RDEIR/SDEIS does not consider the importance and interdependence of UP's rail lines and rail facilities within the larger 710 Corridor, as well as their integral role in the national transportation infrastructure.</u>

NEPA requires a "full and fair discussion of significant environmental impacts" as part of an EIS. 40 C.F.R. § 1502.1; *see also* 42 U.S.C. § 4332 (C); 40 C.F.R. §, 1508.7. This includes analysis of both direct and indirect environmental impacts of the proposed action. 40 C.F.R. § 1508.8. Direct effects are caused by the action and occur at the same time and place. 40 C.F.R. § 1508.8(a). Indirect effects are those caused by the action and are later in time or farther removed in distance, but are still reasonably foreseeable. *See* 40 C.F.R § 1508.8(b). Both include "effects on natural resources and on the components, structures, and functioning of affected ecosystems," as well as "aesthetic, historic, cultural, economic, social, or health [effects]." *Id.* (emphasis added). NEPA requires that federal agencies explain and evaluate economic effects to the extent they are interrelated to the natural or physical environment (*id.* at § 1508.14).

Here, however, the RDEIR/SDEIS does not adequately discuss the effects of the proposed Project on UP rail lines and operations, nor the cascading or spillover effects such impacts could have on the larger interconnected regional and national rail network and UP's goods movement activities. As noted above, UP's rail lines and the East LA Railyard are key components of the vital goods movement economy in Southern California and serve markets across the country. Disruptions of these operations can have cascading impacts not only on rail operations and communities across the Basin, but also in the Ports. For example, UP's San Pedro and Alameda Corridor rail lines both connect the Ports of Los Angeles and Long Beach to the BNSF and UP rail facilities in East Los Angeles, which in turn connect the Ports to the rest of the country. Should operations on the lines be impacted by the Project, traffic at the Ports could be backed up, causing delays in container ship unloading, shipment of containers, etc. Rerouting traffic to trucks or changing the usual rail route could have adverse impacts on neighborhoods not currently affected by goods movement. These changes could result in new and/or more concentrated impacts to residential neighborhoods and other areas not originally included in project baseline assumptions. Even temporary rail disruptions could have far- IP-38-8

[3] *See* RDEIR/SDEIS, pp. 2-13, 2-18.

reaching environmental and economic consequences. Caltrans must provide an analysis of how it will minimize those consequences in its construction and engineering planning. IP-38-8

IV. The RDEIR/SDEIS Does Not Sufficiently Analyze Potential Impacts to Rail Infrastructure and/or Operations Even Though the Project as Currently Proposed Likely: (1) Requires Relocation and/or Redirection of UP's Property, (2) Results in Significant Adverse Impacts, and (3) Obstructs UP's Ongoing and Future Operations in the Region.

The RDEIR/SDEIS analyzes a new set of Project alternatives, including Alternative 1 (No Build), Alternative 5C (Modernization of 710 Freeway)[4], and Alternative 7 (Modernization and Addition of a Clean-Emission Freight Corridor)[5].

The RDEIR/SDEIS acknowledges that the proposed Project will require significant modifications to rail facilities[6], but the discussion is limited to a single half page and focuses on big picture generalities, such as "[r]oadway or railway grade separation structures would be replaced, widened, added and/or removed in order to accommodate lane additions, modified freeway alignments, and reconfigured interchanges. Some intersecting roadways and railroad crossings entail realignment of local roadways and/or railroads."[7] The RDEIR/SDEIS specifies the following UP railroad crossings as requiring modifications under either build alternative:

- Reconstruction of the UP Railroad San Pedro Subdivision at I-405 and at 710, in Long Beach.
- Widening of the UP Railroad San Pedro Subdivision at 710, in South Gate.
- Reconstruction of UP Railroad Patata Industrial Lead at 710, in South Gate, to accommodate the wider freeway.
- Reconstruction of UP Railroad La Habra Subdivision at 710, in Bell, to accommodate the wider freeway.
- Reconstruction of UP Railroad East Yard overpass at 710, in Commerce.[8]

The RDEIR/SDEIS's narrative analysis does not provide much more substantive detail regarding UP rail impacts beyond the general description of rail modifications and noted railroad crossings mentioned above. Appendix O (Concept Plans) includes maps depicting design features of the build alternatives, but it is often unclear from the limited information provided on these maps whether and to what extent UP rail infrastructure or operations may be impacted. Nevertheless, it appears that the following UP right-of-ways and operations in at least ten different locations will be significantly impacted by the proposed Project, as follows: IP-38-9

[4] Alternative 5C proposes to widen the 710 mainline by adding mixed-flow lanes (one in each direction) between I-405 and I-105, and between I-105 and SR-60. Truck bypass lanes are also proposed on 710 through the I-405 interchange. This alternative will modernize the design at the I-405, SR-91, and I-5 interchanges, modernize and reconfigure most local arterial interchanges throughout the 710 corridor, modify freeway access at various locations, and shift the 710 centerline at various locations to reduce right-of-way impacts.

[5] Alternative 7 includes all the components of Alternative 5C described above, but rather than the addition of mixed-flow through lanes and truck bypass lanes, Alternative 7 includes the addition of two separate truck-only lanes in each direction (a total of four lanes, on a combination of viaduct and/or retaining wall structures and at-grade roadbeds adjacent to, or in the median of, the freeway) between Long Beach and Commerce, adjacent to the freeway, approximately 16 miles in length.

[6] *See* RDEIR/SDEIS, pp. 2-13, 2-18.

9. La Habra Sub MP 5.20, DOT 761605L, 710 underpass and Los Angeles River underpass
10. Los Angeles Sub MP 4.87, DOT 811029M, 710 overpass at East LA Intermodal Facility

IP-38-9

Most of the locations identified above appear on the maps to likely involve pier/footing/aerial easements, temporary or permanent track relocations or track shifts, new bridges, temporary construction easements and the like. Many of these impacts may be addressed as part of coordinating and drafting C&M Agreements with Caltrans. Some Project impacts, including those to any grade crossing such as #7 (San Pedro Sub MP), however, will require a CPUC diagnostic process before UP could agree to any new or upgraded work. Other likely Project impacts, such as those to #10 (Commerce/East Yard overpass) will be quite substantial. For instance, the earlier iteration of the proposed Project analyzed in the 2012 EIR/EIS contemplated a 44-foot widening (22 feet on each side of the overpass) and the current proposed Project appears to contemplate a 200-foot widening. As a result, the scope of impacts, and degree of mitigation to address such impacts, will be extensive and much more involved in order to maintain our ability to modernize and increase capacity to meet present and future demand.

The proposed Project's impacts to UP rail lines and infrastructure identified above may result in adverse impacts to air quality, land use, traffic and circulation, noise, community impacts, utilities, aesthetics, hazardous materials, hydrology, plant/animal species, and other environmental considerations and interfere with UP's ongoing and future operations. Additionally, potential closure, relocation and rerouting of existing rail lines will likely result in delays for both rerouted rail traffic and for rail traffic on the lines to which traffic is rerouted (see Section 3(B), above). The RDEIR/SDEIS does not address these potential impacts, nor does it examine how closure, relocation or rerouting of lines will be managed, particularly during construction activities.

IP-38-10

Given the above, UP requests that Caltrans coordinate with UP as soon as possible to identify the suite and scope of potential Project impacts to UP infrastructure and operations and what and whether feasible mitigation measures may be implemented.

IP-38-11

******

In summary, UP is supportive of the proposed 710 Project overall. However, UP opposes the two build alternatives to the extent they impact UP rail infrastructure and operations, absent reaching agreement with Caltrans prior to preparation of the Final EIR/EIS regarding actual potential impacts, feasible mitigations, and compensation to address non-mitigatable impacts, as well as the Project's adherence to UP's operational and rail standards where appropriate. IP-38-12

UP looks forward to an opportunity to work collaboratively with Caltrans going forward in this process. If you have any questions or require additional information from UP, please coordinate directly with Peggy Ygbuhay, Senior Manager Industry & Public Projects – Engineering, at 916-789-5033 and pygbuhay@up.com.

Very truly yours,

ROBERT C. BYLSMA

IP-38-1

Caltrans, as lead agency under CEQA and NEPA (as assigned by the Federal Highway Administration [FHWA]), in cooperation with the Los Angeles County Metropolitan Transportation Authority (Metro), has identified Alternative 1 (No Build) as the Preferred Alternative. Therefore, a Memorandum of Understanding and a Construction and Maintenance Agreement with the Union Pacific Railroad (UP Railroad) will not need to be obtained prior to any construction within or above railroad right-of-way. Please refer to Section 1.1 of this appendix for further discussion on the identification of the Preferred Alternative.

IP-38-2

UP Railroad's opposition to the build alternatives is acknowledged. Please refer to Section 1.1 of this appendix regarding the identification of the Preferred Alternative.

IP-38-3

As stated in Response to Comment IP-38-1, the No Build Alternative has been selected as the Preferred Alternative. Therefore, UP Railroad's operational and rail standards no longer apply.

IP-38-4

As stated in Response to Comment IP-38-1, the No Build Alternative has been selected as the Preferred Alternative. Therefore, there will be no disruption to yard operations and no need for a Construction and Maintenance agreement.

IP-38-5

Please refer to Response to Comment IP-38-4 regarding the need for a Construction and Maintenance agreement. At the time the RDEIR/SDEIS was circulated for public review, specific construction staging details were not available. However, as stated in Response to Comment IP-38-1, the No Build Alternative has been selected as the Preferred Alternative. Therefore, UP Railroad operations will not be impacted.

IP-38-6

Please refer to Response to Comment IP-38-4 regarding disruption to yard operations and the need for a Construction and Maintenance agreement.

IP-38-7

It should be clarified that modifications to UP Railroad rail lines as outlined in Section 2.3.2.1 of the RDEIR/SDEIS are proposed as such in that the geometric design of the build alternatives would require these modifications due to conflicts. In response to this comment, Section 2.3.2.1 of this Final EIR/EIS has been revised to more clearly indicate the modifications to rail facilities proposed as part of the build alternatives. However, as stated in Response to Comment IP-38-1, the No Build Alternative has been selected as the Preferred Alternative and therefore, there will be no conflicts with UP Railroad.

IP-38-8

Please refer to Response to Comment IP-38-4 regarding disruption to yard operations and the need for a Construction and Maintenance agreement.

IP-38-9

Please refer to Response to Comment IP-38-4 regarding disruption to yard operations and the need for a Construction and Maintenance agreement.

IP-38-10

The proposed project's impacts to air quality, land use, traffic and circulation, noise, community impacts, utilities, aesthetics, hazardous materials, hydrology, plant/animal species, and other environmental considerations have been analyzed and disclosed throughout Chapter 3.0, Affected Environment, Environmental Consequences, and Avoidance, Minimization, and/or Mitigation Measures, of the RDEIR/SDEIS. These analyses included all aspects of the build alternatives, including infrastructure such as UP Railroad. However, as stated in Response to Comment IP-38-1, the No Build Alternative has been selected as the Preferred Alternative and therefore, there will be no impacts to UP Railroad facilities.

IP-38-11

As stated in Response to Comment IP-38-1, the No Build Alternative has been selected as the Preferred Alternative and therefore, there will be no impacts to UP Railroad facilities and no mitigation will be implemented.

IP-38-12

UP Railroad's support of the project and opposition to impacts to UP railway infrastructure is acknowledged and noted in the public record. As stated in Response to Comment IP-38-1, the No Build Alternative has been selected as the Preferred Alternative and therefore, there will be no impacts to UP Railroad facilities.

RE: Recirculated Draft Environmental Impact Report (RDEIR)/Supplemental Draft Environmental Impact Study (SDEIS) on the I-710 Corridor

Dear Mr. Kosinski:

On behalf of our Community Outreach and Engagement Team at USC Keck School of Medicine, I submit these comments on the RDEIR/SDEIS for the proposed I-710 Corridor Expansion Project.

As you are well-aware, I have participated in good faith in this environmental review process for more than 15 years. .

CHOICE OF ALTERNATIVE: CALTRANS NEEDS TO ADOPT THE ZERO EMISSION ALTERNATIVE WITH ADDITIONAL COMMUNITY-PREFERRED SUGGESTIONS

I urge Caltrans to select Alternative 7 Design ZE restricting use to zero emission trucks and to adopt all parts of the CA-7 alternative that are legally allowable. I urge that the I-710 not be expanded in terms of any additional lanes for cars, which would thereby put the near-roadway traffic pollution in closer proximity to homes and schools. IP-39-1

Our research at USC shows that near roadway pollution is harmful to health. In Appendix A and Appendix B, I attach two “infographics” we have created at USC, which link to a collection of scientific articles that support the statements in the fact sheets. One of these is on Diesel and Your Health and another is on Near Roadway Pollution. Full text copies of key scientific articles supporting these

documents – and the adverse health effects that will result from expanding the I-710 Freeway -- are also included in Appendices A and B.

I could not find any location within the RDEIR/SDEIS or its Appendices where the adverse health effects of freeway expansion and higher traffic volumes are described. This is a major flaw in the document. IP-39-2

MAJOR ISSUES IN THE RDEIR

1. **THE RDEIR CLAIMS THE PROJECT WILL "IMPROVE AIR QUALITY AND PUBLIC HEALTH.** This was identified as the #1 priority in the "I-710 Tier 2 Community Advisory Committee" which was part of the I-710 Major Corridor Study. This document is inexplicably absent from the RDEIR, so I have attached it as Appendix C. It can also be found here: http://www.gatewaycog.org/gateway/cog-archives/gateway-cities-cog-studies/?item=6390. Please note that the claim of improved air quality can be considered accurate only if the Zero Emissions Truck Corridor, without expansion of the I-710 car lanes, is the adopted alternative. The RDEIR fails to take into consideration the Tier 2 Community Impact Report which stressed the need to reduce noise and air pollution along the I-710 as the very top priorities in selecting alternatives for the I-710 expansion. IP-39-3

2. **EMISSIONS ANALYSES/FAULTY TRUCK VOLUME ASSUMPTIONS/ FAULTY HEALTH RISK AND AIR QUALITY ANALYSIS**
   a. The RDEIR emissions analysis shows emissions with and without the BNSF SCIG (Southern California International Gateway) in operation and the UP ICTF having been expanded. This is an appropriate way to do the evaluation, since it is completely unclear if either project will ever be built/expanded. The RDEIR's HRA, however, grossly underestimates the emissions because it inexplicably assumes that the BNSF SCIG and Union Pacific Intermodal Container Transfer Facility (UP ICTF) *will both be operating*. As a result of assuming that the SCIG and nearby UP ICTF will be expanded (and also inappropriately assuming that these operations will reduce truck volumes on the I-710 even if imports at the Ports go up), the emissions that will result from the I-710 Expansion are grossly underestimated in the HRA. IP-39-4

      The RDEIR's calculation of number of big-rig trucks that would be on the I-710 after the expansion inappropriately assumes that the BNSF Hobart Yard at the northern end of the I-710 will essentially be empty, arguing that containers would instead be going to the new SCIG. Again, this is faulty logic, because a) it is very possible that the SCIG will never be built, as noted in section 3, below, and IP-39-5

b) if the SCIG is built there is zero evidence that the BNSF Hobart Yard will be "empty" due to an expected increase in Port imports. Thus the assumptions in the HRA are, to put it bluntly, "bogus" and they adopt all of the same wrong assumptions that the Port of L.A. and BNSF made in the FEIR for the BNSF SCIG, which were found faulty by a judge in the court case.

IP-39-5

c) The RDEIR/SDEIS's Technical Appendices show the traffic volume figures on which calculations of emissions and health risk are based. We note that the claimed volume of trucks in the future is a great odds with the claims made in the I-710 Major Corridor Study, as noted below:

Mobility and Congestion on the Freeway and in Our Communities

- 35,000 Trucks Per Day from the Two Ports
- 90,000 to 100,000 by Year 2030
- 70,000 Trucks Per Day on I-710 South of I-405 in 2030
- 224,600 Trucks and Cars on the I-710 South of I-405 by 2030

IP-39-6

The following table is from the Traffic Demand Methodology Memo, page 104, and reflects *"Port truck volumes (both directions combined) at six representative locations along the I-710 RDEIR/SDEIS study area."* Note that the I-710 Major Corridor Study calculated 70,000 cars south of the I-405 in 2030, whereas the TDM memo calculates 45,800 with the SCIG/ICTF and 43,000 without those projects. No explanation is provided in the RDEIR/SDEIS for these discrepancies in numbers, which result in underestimating congestion, emissions and health risk.

Table 38. I-710 Daily Port Truck Volumes With / Without SCIG & ICTF Projects

IP-39-6

I-710 Location	No-Project (With SCIG & ICTF Expansion)	Without SCIG & ICTF Expansion	Numeric Difference	Percent Difference
North of Yards	4,500	4,300	-200	-4%
South of Yards	7,000	16,400	9,400	134%
North of I-105	10,500	19,800	9,300	89%
North of SR 91	24,900	33,400	8,500	34%

3. **BNSF SCIG**: There is little reason to assume that the SCIG will actually be built due to a recent court decision – a decision that is cited in the RDEIR/SDEIS. The Court's decision was on March 30, 2016, more than a year before release of the RDEIR/SDEIS: http://www.aqmd.gov/home/library/public-information/2016-news-archives/scig-win-pr: *"The Honorable Barry P. Goode of Contra Costa County Superior Court ruled today that the Port of Los Angeles failed to comply with the California Environmental Quality Act in approving an Environmental Impact Report (EIR) for BNSF Railway's Southern California International Gateway (SCIG) project. The court's decision requires the Port to correct all problems with the environmental analysis before the project can move forward."* Legal proceedings are still underway.

IP-39-7

4. **UP ICTF**: No action had been taken on expansion of the Union Pacific ICTF for at least three years before the RDEIR/SDEIS was released, seeming to make untenable the RDEIR's assumption that the UP ICTF will be expanded and fully operating if/when the I-710 is expanded. Below is an excerpt from minutes of the UP ICTF Joint Powers Authority meeting held November 9, 2016: http://www.ictf-jpa.org/pdf/4-19-17/Item%20B%20-%20Meeting%20Minutes%20from%20November%209%202016.pdf

IP-39-8

> **VI. Progress/Status Report on the Preparation of the Environmental Impact Report**
>
> Mr. Cannon from the Port of Los Angles was present and provided an update on the preparation of the environmental impact report.
>
> Mr. Cannon said that the preparation of the environmental impact report for the ICTF modernization project remains on hold, pending resolution of other outstanding matters.

5. **FAILURE FOR THE RDEIR TO INCLUDE THE DRAMATIC RISE IN TRANSLOADING OF CARGO CONTAINERS ALSO MINIMIZES FUTURE TRUCK VOLUMES ON I-710.** The RDEIR does not take into account the dramatic rise in transload activity over the past 15 years. Transloading changes the truck traffic volumes and truck routing on the I-710 Freeway. In this system, three ocean-going shipping containers from the Ports of L.A. and Long Beach are transferred into two 53-foot domestic containers at facilities near the Ports called "transload centers," to save shipping costs. See calculations from the "Transload Paper" submitted by Andrea Hricko of USC to the proceedings about the FEIR for the BNSF SCIG, Appendix D.

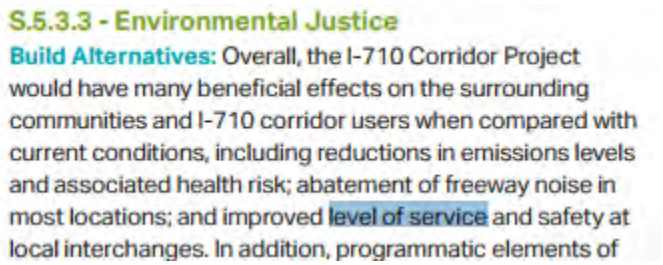
IP-39-9

When there is an increase in "transloading," these containers cannot go to the ICTF and the BNSF SCIG (if these were built/expanded) because currently those railyards handle only 40-foot ocean-going containers, not 53-foot domestic containers. The BNSF Hobart Yard at the very north of I-710 does accept 53 foot containers, and thus much of the transloaded containers heading to rail will go to the Hobart Yard. The *Journal of Commerce*, in a March 3, 2071 article entitled "US transloading growth reshaping cargo routing" by Bill Mongelluzzo, stated: *"... in Southern California, which is the transloading capital of the country, transloading's share of intermodal freight increased from 52 percent in 2011 to 58 percent in 2016, whereas intact intermodal's share dropped from 47 percent in 2011 to 42 percent."* This trend is NOT reflected in the RDEIR, creating a major flaw because it minimizes future truck traffic on the I-710.

In fact, the figures used in the RDEIR's technical appendices are much lower than are reported in the Journal of Commerce article:

> "For 2012, out of the total import loaded containers, 27 percent are transloaded and sent to off-dock railyards (this is called transload to rail) and 13% are transloaded and sent by tractor trailer (this is called transload to truck). For future years transload to rail is expected to increase and the assumption that is used in the model is 30 percent of loaded imports. The transload to truck portion is assumed to remain at 13 percent in the future."

IP-39-9



These figures add up to 43% of loaded imports said to transloaded, whereas the Journal of Commerce reports that 58% were transloaded in 2016. Again, a major flaw in the assumptions that go into the traffic volume (and therefore emissions/health risk) calculations.

6. FAILURE TO CONSIDER 'INDUCED DEMAND' AND THE METHODOLOGIES RECOMMENDED BY SB 743 TO USE VMT (VEHICLES MILED TRAVELED) INSTEAD OF LOS (LEVEL OF SERVICE) IN CALCULATIONS. The RDEIR fails to take into account the well-known problem of "induced demand" – the fact that when a new freeway is built more cars and trucks decide to use it. The words "induced demand" do not even appear in the document. In addition, the words "SB 743" do not appear in the RDEIR/SDEIS, the importance of which is described below.

a. In 2013 the state legislature passed a bill called SB 743, which requires that, in the future, traffic impacts of new transportation projects be evaluated by looking at VMT (vehicle miles traveled) instead of LOS (level of service). VMT looks at excess traffic (induced demand) and LOS at traffic "delays."
b. Despite the clear direction of the SB 743 law for Caltrans and other agencies, the RDEIR/SDEIS looks primarily at LOS instead of at VMT. Granted, Caltrans did not have to do its calculations based on VMT, because the law's full implementation deadlines have not been reached yet. But one might have thought that Caltrans would want to evaluate the true impacts of the I-710 expansion using the metrics that will be law in just a few years. Instead, Caltrans simply ignored the new law (now 4 years since it was passed) and used the old standard of LOS in its calculations. It could have provided at the very least a supplemental analysis of VMT versus LOS in the RDEIR/SDEIS.
c. See Appendix E for reports/studies about Induced Demand.

IP-39-10

d. Here is one example where the RDEIR/SDEIS says there will be "improved levels of service" (i.e., fewer traffic delays)… but it fails to state what the VMT will be on the future expanded 710 freeway.

S.5.3.3 - Environmental Justice

Build Alternatives: Overall, the I-710 Corridor Project would have many beneficial effects on the surrounding communities and I-710 corridor users when compared with current conditions, including reductions in emissions levels and associated health risk; abatement of freeway noise in most locations; and improved level of service and safety at local interchanges. In addition, programmatic elements of

IP-39-11

7. **CONSTRUCTIONS IMPACTS ARE NOT INCLUDED AS PART OF THE HEALTH RISK AND AIR QUALITY ANALYSIS.** These analyses should be redone to show the impacts that emissions will have on residents living along the Corridor. During committee meetings prior to completion of the I-710 Major Corridor Study, the need to include construction emissions was repeatedly mentioned.

IP-39-12

8. **THE COMMUNITY IMPACT ASSESSMENT (CIA) DEMONSTRATES DISPROPROTIONATE IMPACTS, INCLUDING CANCER RISK AND EXPOSURE TO HIGH NOISE LEVELS, ON EJ COMMUNITIES AFTER THE PROJECT IS BUILT.**

   a. ***Air Toxics, PM10 and PM2.5, and Cancer Risk***

      i. The CIA states that air toxics will decrease for build alternatives as compared to 2035 No Build Alternative. But again, these estimates are based on traffic volume projections that assume the building of SCIG and expansion of the UP ICTF, which are faulty assumptions. Therefore, no one can trust the statements that air toxics will decrease.

      IP-39-13

      ii. On the other hand, the CIA states that "tire wear, brake wear and entrained road dust PM10 and PM2.5" will go up.

      IP-39-14

      iii. Cancer risk will be supposedly be reduced overall except "in some near-roadway areas that fall within the locations of the environmental justice populations. See excerpt below from CIA pertaining to **a I, II, III.**

6.3.1.6 CONCLUSIONS

Overall, air toxics generally decrease for the build alternatives as compared to the 2035 No Build Alternative. In the South Coast Air Basin, the incremental emissions of the build alternatives compared to the 2035 No Build scenario are essentially zero for all pollutants with the exception of oxides of nitrogen (NO_X), which decrease under the build alternatives. Along the I-710 freeway, with the exception of NO_X and diesel-related MSAT emissions, exhaust emissions for the build alternatives generally increase compared to the 2035 No Build scenario. The increases in PM_{10} and $PM_{2.5}$ can be attributed to entrained road dust, rather than exhaust emissions (and the modeled analyses included herein are conservative). Cancer risk is lower overall, with the exceptions of some near-roadway areas that fall within the locations of environmental justice populations. Under Alternative 5C, the maximum increase in risk is approximately three in one million. Under Alternative 7, that maximum increase in risk is less than one in one million.

When compared to existing conditions, tire wear, brake wear, and entrained road dust PM_{10} and $PM_{2.5}$ emissions increase under all of the build alternatives. These emissions are proportional to VMT, which increases with the rise in vehicle activity in 2035 as compared to existing conditions. However, when compared to existing conditions, exhaust emissions decrease for all build alternatives with the exception of a slight increase in SO_2 on I-710 under Alternative 7. Cancer risk also decreases under both build alternatives (more so under Alternative 7) as compared to existing conditions, with focused decreases occurring in the AOI and along the I-710 freeway, where environmental justice populations are concentrated.

b. ***Impacts on EJ communities, information from the CIA.***
   i. Impacts include near-roadway pollution that cannot be reduced or eliminated.
   ii. Sensitive receptors impacted include schools and child care centers.
   iii. Mitigation measures are proposed, specifically air filters, ventilation and HVAC systems.

I urge Caltrans to provide filters to any sensitive receptors close to the I-710 Freeway, not just to the schools and child care centers noted below. In addition, the South Coast Air Quality Management District has extensive experience with filters, ventilation systems and HVAC systems and I urge Caltrans to carefully review comments submitted by AQMD to Caltrans specifically about this topic. IP-39-15

that predominantly reside near the I-710 freeway, there are also near-roadway adverse impacts that would disproportionately burden these communities. The AQ/GHG/HRA does not currently identify or propose mitigation measures that would reduce or eliminate increases in pollutant concentrations. Therefore, balancing the beneficial effects of the project, both I-710 Corridor Project build alternatives would have an adverse and disproportionate air quality impact to environmental justice populations. Overall analyses indicate that operationally, Alternative 7 would have a greater impact than Alternative 5C.

Sensitive receptors that have been identified as located within an area of increased pollutants under Alternative 5C include Marlow Park Child Development Center and Inclusion Specialized Programs LLC in the City of Bell Gardens for PM_{10}, and Humphreys Elementary School in the community of East Los Angeles for increased cancer risk. Under Alternative 7, sensitive receptors that have been identified within areas of increase for both annual and 24-hour PM_{10} include the RMR Care Facility, St. John's School, and YMCA First Friendships State Preschool, all in the City of Long Beach; Bell Gardens Elementary School, Briarcrest Nursing Center Nursing Home, Bell Gardens Elementary School, Marlow Park Child Development Center, and Inclusion Specialized Programs LLC Residential Facility, all in the City of Bell Gardens, and Humphreys Elementary School in the community of East Los Angeles. These sensitive receptors have been proposed for mitigation measures. Specifically, provision of new or upgraded air filtration and/or heating, ventilation, and air conditioning (HVAC) systems would be funded by the project as mitigation to reduce exposure to pollutants at these sensitive receptors.

c. The Community Impact Assessment includes information about noise studies that were done in 200 locations of the Corridor. The CIA says the conclusion was that all but three locations with high noise levels could be mitigated by sound walls. The three locations are identified below and they are all considered to be "infeasible" for sound walls because the sound walls would not provide the required 5 dBA noise abatement required by Caltrans' protocol. All are identified as disproportionately impacted EJ communities, as noted in the CIA excerpt immediately below:

> As these impacts are all located in census tracts identified as containing minority and/or low-income populations, it can be concluded that with respect to noise, and after consideration of abatement, both I-710 Corridor Project build alternatives have a disproportionately high and adverse impact to environmental justice populations.

Because of the high noise levels and the nature of the communities, I urge Caltrans to re-consider its protocol and build sound walls to protect residents in East Los Angeles, Paramount and Long Beach as noted below, in excerpt from CIA.

IP-39-16

6.3.2 NOISE

Increases in future (2035) worst-hour noise levels, compared to existing levels, were estimated in a *Traffic Noise Study Report* (2016)[4] at over 200 locations for the I-710 Corridor Project build alternatives.

The need for noise abatement is determined according to which areas may experience noise that approaches or exceeds the Federal Noise Abatement Criteria (NAC). The NAC varies depending on the land use activities being evaluated. The *Traffic Noise Study Report* (2016) found that most parts of the study area will exceed the NAC. As a result, soundwalls are proposed at locations throughout the I-710 Corridor.

For purposes of this analysis, those sound measurement or monitoring locations (receptors) were identified where either build alternative would result in a noise increase that approached or exceeded the NAC, or if a predicted noise level in the design year substantially exceeds the existing noise level (exceeding the existing worst-hour noise level by 12 A-weighted decibels [dBA] or more). The *Traffic Noise Study Report* (2016) identified and recommended acoustically feasible soundwalls. In most cases, the recommended soundwalls would provide adequate noise abatement (defined as five dBA in the Caltrans 2011 *Traffic Noise Analysis Protocol*). Please note that some soundwalls are assumed to be constructed under the Early Action Soundwall Project.

The exceptions are at locations where soundwalls are not considered acoustically feasible because they do not provide the minimum required five dBA noise abatement and are listed as follows:

- Under both Alternatives 5C and 7, along westbound Wardlow Rd. from I-710 to Delta Ave. in the City of Long Beach (designated MSB16A-C), noise abatement in the form of a soundwall (SW-502D) was considered but found to be infeasible as it only provided a two-to-three dBA noise reduction to the residential area. This area falls within a census tract that exceeds the County percentage for minority residents. At this location, the NAC is 67 dBA. The worst-hour noise levels under Alternative 5C range from 65.8–73.6 dBA. The increase in noise levels under Alternative 5C ranges from 7.7–9.2 dBA compared to the existing condition, and 3.5–8.4 dBA compared to Alternative 1. Under Alternative 7, the future worst-hour noise levels at this location range from 65.8–69.8 dBA. The increase in noise levels under Alternative 7 as compared to the existing condition ranges from 5.4–8.6 dBA, and the increase in noise levels as compared to Alternative 1 ranges from 3.5–4.6 dBA.

- Under Alternative 5C, along the edge of shoulder at the southbound I-710 off-ramp at Eastern Ave. in East Los Angeles, noise abatement in the form of a soundwall (SW-519) was considered but found to be infeasible as it did not provide the minimum five dBA noise reduction. This area falls within a census tract that exceeds the County percentages for both minority and low-income residents. The impacted location, labeled SB-71M1 in the NSR, has an NAC of 67 dBA and experiences a worst-hour noise level of 68.8 dBA. The noise increase, as compared to the existing condition, is approximately 5.4 dBA at this location, and a 2.4 dBA increase under Alternative 5C, as compared to Alternative 1, would occur.

- Under Alternative 7, along the northbound freight corridor from SR-91 to Rosecrans Ave. (designated receivers NB-25 through NB-30), noise abatement in the form of a soundwall (SW-708TLN) was considered but found to be infeasible as it only provided a three dBA noise reduction to the residential area east of the Los Angeles River within the City of Paramount. This residential area falls within census tracts that exceed the County percentages for both minority and low-income residents. At these locations, the NAC is 67 dBA, and the worst-hour noise levels under Alternative 7 range from 63.2–69.0 dBA. The noise increase under Alternative 7, as compared to the existing condition, ranges from 6.0–14.3 dBA. When compared to Alternative 1, the increase in noise levels ranges from 4.7–11.1 dBA.

As these impacts are all located in census tracts identified as containing minority and/or low-income populations, it can be concluded that with respect to noise, and after consideration of abatement, both I-710 Corridor Project build alternatives have a disproportionately high and adverse impact to environmental justice populations.

d. Limitations of the Community Impact Assessment. The CIA is based on some technical analyses that were not completed at the time of release of the RDEIR/SDEIS. It is unclear why the RDEIR/SDEIS would be released with incomplete studies that were still being finalized. IP-39-17

9. The RDEIR fails to include the Health Impact Assessment, which was commissioned by the Gateway Cities Council of Governments and which the Project Committee of the I-710 Major Corridor Study voted should be part of the EIR. This situation is completely explained in the NRDC and IP-39-18

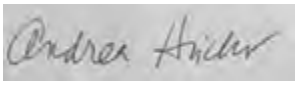
CEHAJ comments submitted as part of the DEIR/DEIS. Caltrans unilaterally decided not to include the HIA in the DEIR. Please note, neither the words HIA nor Health Impact Assessment appear in the RDEIR/SDEIS.

IP-39-18

10. Materials submitted between 2001 and 2015 to Gateway Council of Governments were assumed to be part of the "Administrative Record" in this proceeding.

I participated in dozens of meetings about the I-710 Corridor from 2001 until the present. RDEIR was released. Between 2001 and 2015 I submitted dozens of scientific studies on near-roadway air pollution to the GCCOG staff during committee meetings. Only much later did I learn that none of the articles I submitted were moved forward to the DEIR process. No one ever advised the public that the years of meetings were only to inform the I-710 Major Corridor Study and were not part of the "administrative record" for the EIR/EIS process.

IP-39-19



11. More than 10 years of background documents and records about the I-710 Major Corridor Study and meetings concerning the 710 are missing from the Gateway Cities Council of Governments' website

Dozens of public meetings were held about I-710 Major Corridor, starting in 2001. The websites of Metro and Gateway Cities Council of Governments (GCCOG) have materials only since 2012 on them. Thus no one can read the early documents, public comments, minutes of meetings, etc. When I complained about this, a staff person at Gateway COG found a box/boxes of such materials onsite, but I did not have time to go to Paramount to look through them prior to submitting these comments. It seems simply inappropriate to remove more than 10 years of records of proceedings from the Gateway Cities COG website before the RDEIR/SDEIS of the I-710 was certified.

IP-39-20

Thank you for the opportunity to submit these comments.

Sincerely yours,

Andrea Hricko
Professor Emerita of Preventive Medicine
USC Keck School of Medicine

WHAT is in diesel exhaust?

Diesel exhaust contains more than 40 toxic chemicals

Very high numbers of tiny ultrafine particles

High levels of harmful gases, such as nitrogen dioxide

HOW does diesel exhaust affect our health?

Short-term effects:

Irritation to the eyes, nose, throat and lungs

Cough, headache, nausea

Long-term effects:

Lung cancer

Bladder cancer

Worse allergies, asthma attacks, and lung illnesses

Heart disease

Get involved

City
County
State
National

Cleaner technology is available now. Trucks, buses and yard equipment can be ZERO EMISSIONS

Lower Emissions = Fewer Health Impacts

Health Effects of Diesel Exhaust

A fact sheet by
Cal/EPA's Office of Environmental Health Hazard Assessment and
The American Lung Association of California.

Diesel fuel is widely used throughout our society. It powers trucks that deliver products to our communities, buses that carry us to school and work, agricultural equipment that plants and harvests our food, and backup generators that can provide electricity during emergencies. It is also used for many other applications. Diesel engines have historically been more versatile and cheaper to run than gasoline engines or other sources of power. Unfortunately, the exhaust from these engines contains substances that can pose a risk to human health.

In 1998, the California Environmental Protection Agency's Office of Environmental Health Hazard Assessment (OEHHA) completed a comprehensive health assessment of diesel exhaust. This assessment formed the basis for a decision by the California Air Resources Board (ARB) to formally identify particles in diesel exhaust as a toxic air contaminant that may pose a threat to human health. The American Lung Association of California (ALAC) and its 15 local associations work to prevent lung disease and promote lung health. Since 1904, the American Lung Association has been fighting lung disease through education, community service, advocacy and research.

This fact sheet by OEHHA and ALAC provides information on health hazards associated with diesel exhaust.

Diesel exhaust contains more than 40 toxic air contaminants

What is diesel exhaust?

Diesel exhaust is produced when an engine burns diesel fuel. It is a complex mixture of thousands of gases and fine particles (commonly known as soot) that contains more than 40 toxic air contaminants. These include many known or suspected cancer-causing substances, such as benzene, arsenic and formaldehyde. It also contains other harmful pollutants, including nitrogen oxides (a component of urban smog).

How are people exposed to diesel exhaust?

Diesel exhaust particles and gases are suspended in the air, so exposure to this pollutant occurs whenever a person breathes air that contains these substances. The prevalence of diesel-powered engines makes it almost impossible to avoid exposure to diesel exhaust or its byproducts, regardless of whether you live in a rural or urban setting. However, people living and working in urban and industrial areas are more likely to be exposed to this pollutant. Those spending time on or near roads and freeways, truck loading and unloading operations, operating diesel-powered machinery or

working near diesel equipment face exposure to higher levels of diesel exhaust and face higher health risks.

What are the health effects of diesel exhaust?

As we breathe, the toxic gases and small particles of diesel exhaust are drawn into the lungs. The microscopic particles in diesel exhaust are less than one-fifth the thickness of a human hair and are small enough to penetrate deep into the lungs, where they contribute to a range of health problems.

Diesel exhaust and many individual substances contained in it (including arsenic, benzene, formaldehyde and nickel) have the potential to contribute to mutations in cells that can lead to cancer. In fact, long-term exposure to diesel exhaust particles poses the highest cancer risk of any toxic air contaminant evaluated by OEHHA. ARB estimates that about 70 percent of the cancer risk that the average Californian faces from breathing toxic air pollutants stems from diesel exhaust particles.

Diesel exhaust increases the risk of cancer…

In its comprehensive assessment of diesel exhaust, OEHHA analyzed more than 30 studies of people who worked around diesel equipment, including truck drivers, railroad workers and equipment operators. The studies showed these workers were more likely to develop lung cancer than workers who were not exposed to diesel emissions. These studies provide strong evidence that long-term occupational exposure to diesel exhaust increases the risk of lung cancer. Using information from OEHHA's assessment, ARB estimates that diesel-particle levels measured in California's air in 2000 could cause 540 "excess" cancers (beyond what would occur if there were no diesel particles in the air) in a population of 1 million people over a 70-year lifetime. Other researchers and scientific organizations, including the National Institute for Occupational Safety and Health, have calculated cancer risks from diesel exhaust that are similar to those developed by OEHHA and ARB.

Exposure to diesel exhaust can have immediate health effects. Diesel exhaust can irritate the eyes, nose, throat and lungs, and it can cause coughs, headaches, light-headedness and nausea. In studies with human volunteers, diesel exhaust particles made people with allergies more susceptible to the materials to which they are allergic, such as dust and pollen. Exposure to diesel exhaust also causes inflammation in the lungs, which may aggravate chronic respiratory symptoms and increase the frequency or intensity of asthma attacks.

… And it can cause coughs and aggravate asthma

Diesel engines are a major source of fine-particle pollution. The elderly and people with emphysema, asthma, and chronic heart and lung disease are especially sensitive to fine-particle pollution. Numerous studies have linked elevated particle levels in the air to increased hospital admissions, emergency room visits, asthma attacks and premature deaths among those suffering from respiratory problems. Because children's lungs and respiratory systems are still developing, they are also more susceptible than healthy adults to fine particles. Exposure to fine particles is associated with increased frequency of childhood illnesses and can also reduce lung function in children.

Like all fuel-burning equipment, diesel engines produce nitrogen oxides, a common air pollutant in California. Nitrogen oxides can damage lung tissue, lower the body's resistance to respiratory infection and worsen chronic lung diseases, such as asthma. They also react with other pollutants in the atmosphere to form ozone, a major component of smog.

What is being done to reduce the health risks from diesel exhaust?

Improvements to diesel fuel and diesel engines have already reduced emissions of some of the pollutants associated with diesel exhaust. However, diesel exhaust is still one of the most widespread and toxic substances in California's air.

ARB's Diesel Risk Reduction Plan, when fully implemented, will result in a 75 percent reduction in particle emissions from diesel equipment by 2010 (compared to 2000 levels), and an 85 percent reduction by 2020. The plan calls for the use of cleaner-burning diesel fuel, retrofitting of existing engines with particle-trapping filters, and the use in new diesel engines of advanced technologies that produce nearly 90 percent fewer particle emissions, as well as the use of alternative fuels.

Diesel exhaust contributes to smog and fine-particle pollution

The use of other fuels, such as natural gas, propane and electricity offer alternatives to diesel fuel. All of them produce fewer polluting emissions than current formulations of diesel fuel. As a result of ARB and local air-quality regulations, public transit agencies throughout California are using increasing numbers of passenger buses that operate with alternative fuels or retrofitted equipment.

Carcinogenicity of diesel-engine and gasoline-engine exhausts and some nitroarenes

In June, 2012, 24 experts from seven countries met at the International Agency for Research on Cancer (IARC; Lyon, France) to assess the carcinogenicity of diesel and gasoline engine exhausts, and some nitroarenes. These assessments will be published as Volume 105 of the IARC Monographs.[1]

Diesel engines are used for on-road and non-road transport (eg, trains, ships) and (heavy) equipment in various industrial sectors (eg, mining, construction), and in electricity generators, particularly in developing countries. Gasoline engines are used for cars and hand-held equipment (eg, chainsaws).

Emissions from these engines are complex, with varying composition. The gas phase consists of carbon monoxide, nitrogen oxides, and volatile organic compounds such as benzene and formaldehyde. Particles consist of elemental and organic carbon, ash, sulfate, and metals. Polycyclic aromatic hydrocarbons and nitroarenes are distributed over the gas and the particle phase. The qualitative and quantitative composition of exhausts depends on the fuel, the type and age of the engine, the state of its tuning and maintenance, the emission control system, and pattern of use. Diesel-engine exhaust from engines with no or limited emission controls contains more particulate matter.[2]

In the past two decades, progressively tighter emission standards for on-road vehicles, introduced in North America, Europe, and elsewhere, have triggered advances in diesel technology that resulted in lower emission of particulate matter, nitrogen oxides, and hydrocarbons. Emission standards in non-road applications are lagging and therefore are still largely uncontrolled today. Moreover, in many less developed countries standards are not in place for both on-road and non-road use of diesel and gasoline engines.

The most influential epidemiological studies assessing cancer risks associated with diesel-engine exhausts investigated occupational exposure among non-metal miners, railroad workers, and workers in the trucking industry. The US miners study included a cohort analysis[3] and a nested case–control analysis that was adjusted for tobacco smoking.[4] Both showed positive trends in lung cancer risk with increasing exposure to diesel exhaust, as quantified via estimated elemental carbon as a proxy of exposure. Trends were significant in the nested case–control study, with a 2–3-fold increased risk in the highest categories of cumulative or average exposure. This study provides some of the strongest evidence of an association between exposure to diesel-engine exhaust and lung cancer since there were few potential confounding exposures in these underground mines, and high diesel exposures were well documented in current surveys.

In another US study,[5] a 40% increased risk for lung cancer was observed in railroad workers exposed to diesel exhaust compared with individuals exposed to low levels of or no emissions. Indirect adjustment for smoking suggested that differences in smoking could not have influenced this excess risk substantially. This study was later extended by estimating diesel exposure on the basis of work history and history of dieselisation of different railroads, and showed a significantly increased risk for exposed workers of 70–80%; risk increased with duration of exposure but not with cumulative exposure.[6]

A large cohort study in the US trucking industry[7] reported a 15–40% increased lung cancer risk in drivers and dockworkers with regular exposure to diesel exhaust. There was a significant trend of increasing risks with longer duration of employment, with 20 years of employment roughly doubling the risk after adjusting for tobacco smoking. When this study was extended with an exposure assessment involving contemporary measurements and exposure reconstruction on the basis of elemental carbon, positive trends were observed for cumulative but not average exposure. These trends were more pronounced when adjustment for duration of work was included.[8]

The findings of these cohort studies were supported by those in other occupational groups and by case–control studies including various occupations involving exposure to diesel-engine exhaust. A positive exposure–response relationship was found in several studies from Europe and the USA, many of which were adjusted for tobacco smoking. Most notably, a pooled analysis of 11 population-based case–control studies from Europe and Canada showed a smoking-adjusted increased risk for lung cancer after exposure to diesel engine exhaust, which was assessed by a job exposure matrix, and a positive dose response in terms of both a cumulative exposure index and duration of exposure.[9]

These epidemiological studies support a causal association between exposure to diesel-engine exhaust and lung cancer. An increased risk for bladder cancer was also noted in many but not all available case–control studies. However, such risks were not observed in cohort studies. The Working Group concluded that there was "sufficient evidence" in humans for the carcinogenicity of diesel-engine exhaust.

The diesel-engine exhausts and their extracts used in carcinogenicity studies with experimental animals were generated from fuels and diesel engines produced before 2000. The studies were considered by type of

*Strong mechanistic evidence contributed to the overall evaluation.

Table: **Evaluation of some nitroarenes**

exposure: whole diesel-engine exhaust; gas-phase diesel-engine exhaust (with particles removed); and extracts of diesel-engine exhaust particles. Whole diesel-engine exhaust caused an increased incidence of lung tumours in rats.[10] Diesel-engine exhaust particles instilled intratracheally caused benign and malignant lung tumours in rats,[11] and the particle extracts also caused lung carcinomas in rats and sarcomas at the injection site in mice.[12,13] Gas-phase diesel-engine exhaust did not increase incidence of respiratory tumours in any species tested. The Working Group concluded that there was "suffi cient evidence" in experimental animals for the carcinogenicity of whole diesel-engine exhaust, of diesel-engine exhaust particles and of extracts of diesel-engine exhaust particles.

Diesel-engine exhaust, diesel-exhaust particles, diesel-exhaust condensates, and organic solvent extracts of diesel-engine exhaust particles induced, in vitro and in vivo, various forms of DNA damage, including bulky adducts, oxidative damage, strand breaks, unscheduled synthesis, mutations, sister chromatid exchange, morphological cell transformation in mammalian cells, and mutations in bacteria.[14] Increased expression of genes involved in xenobiotic metabolism, oxidative stress, inflammation, antioxidant response, apoptosis, and cell cycle in mammalian cells was observed.

Positive genotoxicity biomarkers of exposure and effect were also observed in humans exposed to diesel engine exhaust. The Working Group concluded that there is "strong evidence" for the ability of whole diesel-engine exhaust to induce cancer in humans through genotoxicity.

Gasoline exhaust and cancer risk was investigated in only a few epidemiological studies and, because of the diffi culty to separate effect of diesel and gasoline exhaust, evidence for carcinogenicity was evaluated as "inadequate".

The Working Group considered the animal carcinogenicity studies of gasoline-engine exhaust by type of exposure: whole gasoline-engine exhaust; and extracts of gasoline-engine exhaust condensate. Organic extracts of gasoline engine-exhaust condensate induced a significant increase in lung carcinomas and papillomas of the skin in mice.[15] In rats, the gasoline-exhaust condensate induced a significant increase in lung carcinomas.[16] The Working Group concluded that there was "suffi cient evidence" in experimental animals for the carcinogenicity of condensates of gasoline-engine exhaust.

Gasoline-engine exhaust induced chromosomal damage in mice, and changes in gene expression in rat lung that involved pathways related to xenobiotic metabolism and inflammation. In mammalian cells, gasoline-engine exhaust particles and organic extracts thereof induce DNA adducts, DNA strand breaks, oxidative DNA damage, chromosomal aberrations, and morphological cell transformation, as well as gene mutations in bacteria. In mammalian cells, extracts of gasoline-exhaust engine particles altered expression of genes involved in inflammation, xenobiotic metabolism, tumour progression, and cell cycle. The gaseous phase of gasoline-engine exhaust was mutagenic to bacteria. The Working Group concluded that there is "strong evidence" for a genotoxic mechanism for the carcinogenicity of organic solvent extracts of particles from gasoline engine exhaust.

In conclusion, the Working Group classified diesel engine exhaust as "carcinogenic to humans" (Group 1) and gasoline engine exhaust as "possibly carcinogenic to humans" (Group 2B).

Evaluations for ten nitroarenes, all of which have been detected in diesel-engine exhaust, are shown in the table. Biomonitoring studies have shown that workers and the general population are exposed to these substances.[17–19] All the nitroarenes were genotoxic to various extents in different assays. The Working Group reaffirmed the Group 2B classification of seven. Strong evidence for genotoxicity led to an upgrade of 3-nitrobenzanthrone to Group 2B, and similar findings in human cells led to an upgrade of 1-nitropyrene and 6-nitrochrysene to Group 2A.

The Report on Diesel Exhaust

This page last reviewed July 21, 2015

Findings of the Scientific Review Panel On

The Report on Diesel Exhaust

As Adopted at the Panel's April 22, 1998 Meeting

Pursuant to Health and Safety Code section 39661, the Scientific Review Panel (SRP / Panel) has reviewed the report *Proposed Identification of Diesel Exhaust as a Toxic Air Contaminant* by the staffs of the California Air Resources Board (ARB or Board) and the Office of Environmental Health Hazard Assessment (OEHHA) describing the public exposure to, and health effects of, diesel exhaust. The Panel members also reviewed the public comments received on this report.

Panel members participated in workshops devoted to discussion of the exposure and health issues associated with diesel exhaust in September 1994, January 1996, July 1997, and March 1998. The SRP reviewed the issues at its meetings in October 1997 and April 1998. A special meeting of the SRP was held on March 11, 1998, to hear testimony on health issues including the quantitative risk assessment from highly respected scientists invited by the Panel. Based on these reviews and information provided at scientific workshops and meetings, the SRP makes the following findings pursuant to Health and Safety Code section 39661:

Exposure Related Conclusions:

1. Diesel exhaust is a complex mixture of gases and fine particles emitted by a diesel-fueled internal combustion engine.

2. The gaseous fraction is composed of typical combustion gases such as nitrogen, oxygen, carbon dioxide, and water vapor. However, as a result of incomplete combustion, the gaseous fraction also contains air pollutants such as carbon monoxide, sulfur oxides, nitrogen oxides, volatile organics, alkenes, aromatic hydrocarbons, and aldehydes, such as formaldehyde and 1,3-butadiene and low-molecular weight polycyclic aromatic hydrocarbons (PAH) and PAH-derivatives.

3. One of the main characteristics of diesel exhaust is the release of particles at a markedly greater rate than from gasoline-fueled vehicles, on an equivalent fuel energy basis. The particles are mainly aggregates of spherical carbon particles coated with inorganic and organic substances. The inorganic fraction primarily consists of small solid carbon (or elemental carbon) particles ranging from 0.01 to 0.08 microns in diameter. The organic fraction consists of soluble organic compounds such as aldehydes, alkanes and alkenes, and high-molecular weight PAH and PAH-derivatives, such as nitro-PAHs. Many of these PAHs and PAH-derivatives, especially nitro-PAHs, have been found to be potent mutagens and carcinogens. Nitro-PAH compounds can also be formed during transport through the atmosphere by reactions of adsorbed PAH with nitric acid and by gas-phase radical-initiated reactions in the presence of oxides of nitrogen.

4. Diesel exhaust includes over 40 substances that are listed by the United States Environmental Protection Agency (U.S. EPA) as hazardous air pollutants and by the ARB as toxic air contaminants. Fifteen of these substances are listed by the International Agency for Research on Cancer (IARC) as carcinogenic to humans, or as a probable or possible human carcinogen. Some of these substances are: acetaldehyde; antimony compounds; arsenic; benzene; beryllium compounds; bis(2-ethylhexyl)phthalate; dioxins and dibenzofurans; formaldehyde; inorganic lead; mercury compounds; nickel; POM (including PAHs); and styrene.

5. Almost all of the diesel particle mass is in the fine particle range of 10 microns or less in diameter (PM10). Approximately 94 percent of the mass of these particles are less than 2.5 microns in diameter. Because of their small size, these particles can be inhaled and a portion will eventually become trapped within the small airways and alveolar regions of the lung.

6. The estimated population-weighted average outdoor diesel exhaust PM10 concentration in California for 1995 is 2.2 microgram per cubic meter ($\mu g/m^3$). Several independent studies have reported similar outdoor air diesel exhaust PM10 concentrations. The 1995 estimated average indoor exposure concentration is approximately 1.5 $\mu g/m^3$.

7. The population time-weighted average total air exposure to diesel exhaust particle concentrations across all environments (including outdoors) is estimated to be 1.5 $\mu g/m^3$ in 1995. This total exposure estimate may underestimate many Californians' actual total exposure because it excludes elevated exposures near roadways, railroad tracks, and inside vehicles. Near-source exposures to diesel exhaust may be as much as five times higher than the 1995 population time-weighted average total air exposure. It also excludes other routes of exposure to diesel exhaust, such as ingestion and dermal absorption.

8. Diesel engine exhaust contains small carbonaceous particles and a large number of chemicals that are adsorbed onto these particles or present as vapors. These particles have been the subject of many studies because of their adverse effects on human health and the environment. A recent study conducted for the Health Effects Institute showed that, despite a substantial reduction in the weight of the total particulate matter, the total number of particles from a 1991-model engine was 15 to 35 times greater than the number of particles from a 1988 engine when both engines were operated without emission control devices. This suggests that more fine particles, a potential health concern, could be formed as a result of new technologies. Further study is needed since the extent of these findings only measured exhaust from two engines and engine technologies.

9. The major sources of diesel exhaust in ambient outdoor air are estimated to emit approximately 27,000 tons per year in 1995. On-road mobile sources (heavy-duty trucks, buses, light-duty cars and trucks) contribute the majority of total diesel exhaust PM10 emissions in California. Other mobile sources (mobile equipment, ships, trains, and boats) and stationary sources contribute the remaining emissions.

10. Significant progress has been made as a result of federal and state regulations that have addressed particulate matter levels from diesel engines. Emissions of on-road mobile source diesel exhaust PM10 in California are expected to decline by approximately 85 percent from 1990 to 2010 as a result of mobile source regulations already adopted by the ARB.

11. The results of a study funded by the ARB at the University of California, Riverside, indicate that the diesel exhaust from the new fuel tested contained the same toxic air contaminants as the old fuel, although their concentrations and other components may differ. Further research would be helpful to quantify the amounts of specific compounds emitted from a variety of engine technologies, operating cycles, and fuel to characterize better any differences between old and new fuels and technologies.

Health Effects Associated with Diesel Exhaust:

12. A number of adverse short-term health effects have been associated with exposures to diesel exhaust. Occupational exposures to diesel exhaust particles have been associated with significant cross-shift decreases in lung function. Increased cough, labored breathing, chest tightness, and wheezing have been associated with exposure to diesel exhaust in bus garage workers. A significant increase in airway resistance and increases in eye and nasal irritation were observed in human volunteers following one-hour chamber exposure to diesel exhaust. In acute or subchronic animal studies, exposure to diesel exhaust particles induced inflammatory airway changes, lung function changes, and increased the animals' susceptibility to infection.

13. A number of adverse long-term noncancer effects have been associated with exposure to diesel exhaust. Occupational studies have shown that there may be a greater incidence of cough, phlegm and chronic bronchitis among those exposed to diesel exhaust than among those not exposed. Reductions in pulmonary function have also been reported following occupational exposures in chronic studies. Reduced pulmonary function was noted in monkeys during long-term exposure. Histopathological changes in the lung of diesel-exposed test animals reflect inflammation of the lung tissue. These changes include dose-dependent proliferations of Type II epithelial cells, marked infiltration of macrophages, plasma cells and fibroblasts into the alveolar septa, thickening of the alveolar walls, alveolar proteinosis, and focal fibrosis.

14. Studies have shown that diesel exhaust particles can induce immunological reactions and localized inflammatory responses in humans, as well as acting as an adjuvant for pollen allergy. Intranasal challenge with diesel exhaust particles in human volunteers resulted in increased nasal IgE antibody production and a significant increase in mRNA for pro-inflammatory cytokines. Co-exposure to diesel exhaust particles and ragweed pollen resulted in a nasal IgE response greater than that following pollen or diesel exhaust particles alone. Effects of intratracheal, intranasal, and inhalation exposures of laboratory animals are supportive of the findings in humans. These effects include eosinophilic infiltration into bronchi and bronchioles, elevated IgE response, increased mucus secretion and respiratory resistance, and airway constriction.

15. Based on the animal studies, the U.S. EPA determined a chronic inhalation Reference Concentration value of 5 $\mu g/m^3$ for noncancer effects of diesel exhaust. This estimate takes into consideration persons who may be more sensitive than others to the effects of diesel exhaust. The report supports the recommendation of 5 $\mu g/m^3$ as the California Reference Exposure Level (REL) (Table 1). It should be noted that this REL may need to be lowered further as more data emerge on potential adverse noncancer effects from diesel exhaust.

16. Diesel exhaust contains genotoxic compounds in both the vapor phase and the particle phase. Diesel exhaust particles or extracts of diesel exhaust particles are mutagenic in bacteria and in mammalian cell systems, and can induce chromosomal aberrations, aneuploidy, and sister chromatid exchange in rodents and in human cells *in vitro*. Diesel exhaust particles induced unscheduled DNA synthesis *in vitro* in mammalian cells. DNA adducts have been isolated from calf thymus DNA *in vitro* following treatment with diesel exhaust particle extracts. DNA adducts have been shown to increase following inhalation exposure of rodents and monkeys to whole diesel exhaust. Elevated levels of DNA adducts have been associated with occupational exposure to diesel exhaust. Results of inhalation bioassays in the rat, and with lesser certainty in mice, have demonstrated the carcinogenicity of diesel exhaust in test animals, although the mechanisms by which diesel exhaust induces lung tumors in animals remains uncertain.

17. Over 30 human epidemiological studies have investigated the potential carcinogenicity of diesel exhaust. These studies, on average, found that long-term occupational exposures to diesel exhaust were associated with a 40 percent increase in the relative risk of lung cancer. The lung cancer findings are consistent and the association is unlikely to be due to chance. These epidemiological studies strongly suggest a causal relationship between occupational diesel exhaust exposure and lung cancer.

18. Other agencies or scientific bodies have evaluated the health effects of diesel exhaust. The National Institute of Occupational Safety and Health first recommended in 1988 that whole diesel exhaust be regarded as a potential occupational carcinogen based upon animal and human evidence. The International Agency for Research on Cancer (IARC) concluded that diesel engine exhaust is probably carcinogenic to humans and classified diesel exhaust in Group 2A. Based upon the IARC findings, in 1990, the State of California under the Safe Drinking Water and Toxic Enforcement Act of 1986 (Proposition 65) identified diesel exhaust as a chemical "known to the State to cause cancer." The U.S. EPA has proposed a conclusion similar to IARC in their draft documents. The 1998 draft U.S. EPA document concluded similarly that there was sufficient animal evidence of carcinogenicity and that the human evidence was limited.

19. There are data from human epidemiological studies of occupationally exposed populations which are useful for quantitative risk assessment. The estimated range of lung cancer risk (upper 95% confidence interval) based on human epidemiological data is 1.3×10^{-4} to 2.4×10^{-3} $(\mu g/m^3)^{-1}$ (Table 2). After considering the results of the meta-analysis of human studies, as well as the detailed analysis of railroad workers, the SRP concludes that 3×10^{-4} $(\mu g/m^3)^{-1}$ is a reasonable estimate of unit risk expressed in terms of diesel particulate. Thus this unit risk value was derived from two separate approaches which yield similar results. A comparison of estimates of risk can be found in Table 3.

20. Based on available scientific information, a level of diesel exhaust exposure below which no carcinogenic effects are anticipated has not been identified.

21. Based on available scientific evidence, as well as the results of the risk assessment, we conclude that diesel exhaust be identified as a Toxic Air Contaminant.

22. As with other substances evaluated by this Panel and after reviewing the field of published peer reviewed research studies on diesel exhaust, additional research is appropriate to clarify further the health effects of diesel exhaust. This research may have significance for estimating the unit risk value.

23. The Panel, after careful review of the February 1998 draft SRP version of the ARB report, *Proposed Identification of Diesel Exhaust as a Toxic Air Contaminant*, as well as the scientific procedures and methods used to support the data, the data itself, and the conclusions and assessments on which the Report is based, finds this report with the changes specified during our October 16, 1997, meeting and as a result of comments made at the March 11, 1998, meeting, is based upon sound scientific knowledge, methods, and practices and represents a complete and balanced assessment of our current scientific understanding.

For these reasons, we agree with the science presented in Part A by ARB and Part B by OEHHA in the report on diesel exhaust and the ARB staff recommendation to its Board that diesel exhaust be listed by the ARB as a Toxic Air Contaminant.

I certify that the above is a true and correct copy of the findings adopted by the Scientific Review Panel on April 22, 1998.

Sincerely,
/s/
John R. Froines, Ph.D.
Acting Chairman
Scientific Review Panel

Occupational diesel exhaust exposure as a risk factor for chronic obstructive pulmonary disease

Jaime E. Hart[a], *Ellen A. Eisen*[b,c], *and Francine Laden*[a,c,d]

Purpose of review
Chronic obstructive pulmonary disease (COPD) is a major source of morbidity and mortality worldwide. Although cigarette smoking is the major cause of COPD, occupational exposures have emerged as an important risk factor, especially in nonsmokers. In this review, we assess the state of the literature on the association of COPD with a specific occupational exposure, diesel exhaust.

Recent findings
A large body of literature links general occupational exposures to dust and fumes with an increased risk of COPD, particularly in nonsmokers. Few studies, however, have explicitly examined the role of occupational diesel exhaust exposures to COPD risk. Suggestive recent findings link occupational diesel exposures to an increased risk of COPD.

Summary
The available literature directly examining the effects of occupational diesel exhaust on risk of COPD is quite small, but does suggest that increasing exposures are associated with increasing risk. Additional research, with more advanced exposure metrics, is needed to fully elucidate this association.

Keywords
chronic obstructive pulmonary disease, diesel exhaust, fumes, occupation

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a common disease that results in considerable morbidity and mortality in the United States and worldwide. Its clinical course is characterized by acute exacerbations resulting in large numbers of physician and hospital outpatient visits (8 million), emergency department visits (1.5 million), and hospitalizations (726 000) in the USA [1]. COPD was the underlying cause in approximately 1 in 20 deaths in the USA in 2006 and was the fourth leading cause of death worldwide in 2008 [1–3].

Occupational exposures, especially to dust and fumes, have been identified as potentially significant risk factors for COPD [4]. Since 1989, a number of review articles have synthesized the association of occupation on risk of COPD and determined that it is an important risk factor [5–15]. Numerous studies have attempted to determine the population attributable risk percentage to account for the percentage of COPD due specifically to work-related factors. Estimates of this percentage for the general population range from 0 to 37%, with a median value of 15% [4]. Higher percentages were reported for nonsmokers (12–53%) [16–20]. In a recent analysis, an 8.8% reduction in occupational exposures to dust/gases/fumes would result in an estimated 20% reduction in the prevalence of COPD worldwide [21]. All of these reviews have highlighted the importance of exploring occupational risk factors for COPD.

Recent attention has focused specifically on diesel exhaust exposure as an important occupational risk factor. Diesel exhaust is a complex mixture of particulate matter and gases, and includes particles less than 1.0 μm in diameter with mutagenic and polycyclic aromatic hydrocarbon (PAH) carcinogenic compounds adsorbed to a carbon

KEY POINTS

- A large body of literature links general occupational exposures to dust and fumes with an increased risk of COPD, particularly in nonsmokers.
- The available literature directly examining the effects of occupational diesel exhaust on risk of COPD is quite small, but does suggest that increasing exposures are associated with increasing risk.
- Additional research, with more advanced exposure metrics, is needed to fully elucidate the impact of occupational diesel exposure on COPD risk.

core and ultrafine particles made up of condensed organics [22]. Individuals in a variety of occupations, including transportation (railroads, trucks, and buses), construction, mining, and maintenance, are routinely exposed to diesel exhaust. There is no one accepted measure specific to diesel exhaust. However, work in an exposed job, as determined by industrial hygiene assessment or expert review, or self-reported exposure to occupational dust and fumes or specifically to diesel exhaust have been used in the epidemiologic literature to assess associations with COPD.

The goal of this review is to assess the body of literature on the association of occupational diesel exhaust exposure and risk of COPD incidence and mortality. Results from observational epidemiology studies are presented, with emphasis on more recent publications. They are organized by specificity of exposure assessment for diesel exhaust.

OCCUPATIONS WITH LIKELY DIESEL EXHAUST EXPOSURE AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE RISK

One of the most comprehensive studies of occupations with exposure to diesel exhaust and COPD was based on data from the US Third National Health and Nutrition Examination Study (NHANES III). Using data on occupation and industry collected as part of the standardized interview, the association between 25 *a priori* selected occupational categories and COPD defined based on lung function testing was examined [18]. After adjustment for age, sex, race/ethnicity, body mass index, smoking (status and pack-years), educational level, and socioeconomic status, elevated odds ratios (ORs) were observed for industries with likely diesel exhaust exposure, such as construction [OR 1.3, 95% confidence interval (95% CI) 0.8–2.3] and transportation and trucking (OR 1.2, 95% CI 0.8–2.0), as shown in Fig. 1. The odds ratios were higher in never-smokers (construction OR 3.5; 95% CI 0.9–14.0, transportation and trucking OR 2.0; 95% CI 0.3–15.0). Odds ratios were also elevated when the analysis was performed by occupation, with ORs for occupations such as vehicle mechanics, transportation, construction workers, and motor vehicle operators ranging from 1.2 to 2.0 in the total sample and 2.1 to 3.4 in never-smokers.

In a cohort study [23] of workers in the US railroad industry, worker job histories were classified into years of work in different job categories with varying levels of exposure to diesel exhaust from locomotives. After adjusting for age, calendar year, and time since leaving work, each additional year of work in a job with locomotive exposure was associated with a 2.5% (95% CI 0.9–4.2%) increased risk of COPD mortality. These associations were robust to indirect control for cigarette smoking. These were similar to findings from an earlier case–control study in the same industry, where increasing years of work were associated with an OR of 1.02 (95% CI 1.01–1.04) [24].

DIESEL EXHAUST EXPOSURE AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE RISK

Few studies have had the ability to examine the effects of diesel exhaust specifically on the risk of COPD [25]. However, in a recent case–control study of participants in the Kaiser Permanente Northwest health maintenance organization, COPD cases and controls completed a questionnaire with information on demographics, family history, and a detailed work history [26]. As part of the job history, individuals reported routine (weekly) exposures to diesel exhaust. In addition, industrial hygienists assessed the potential for diesel exhaust exposure based on a review of the jobs and industries each individual reported. In logistic regression models adjusted for age and sex, individuals with any diesel exhaust had an OR of 1.9 (95% CI 1.3–3.0) compared to those with no exposure. The risk was higher among never-smokers (OR 6.4, 95% CI 1.3–31.6) and among those rated by the industrial hygienists to have moderate exposure.

OCCUPATIONAL DUST/FUME EXPOSURE AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE RISK

There are hundreds of studies looking at occupational dust/fume exposure. Excellent summaries of the literature were conducted by the American

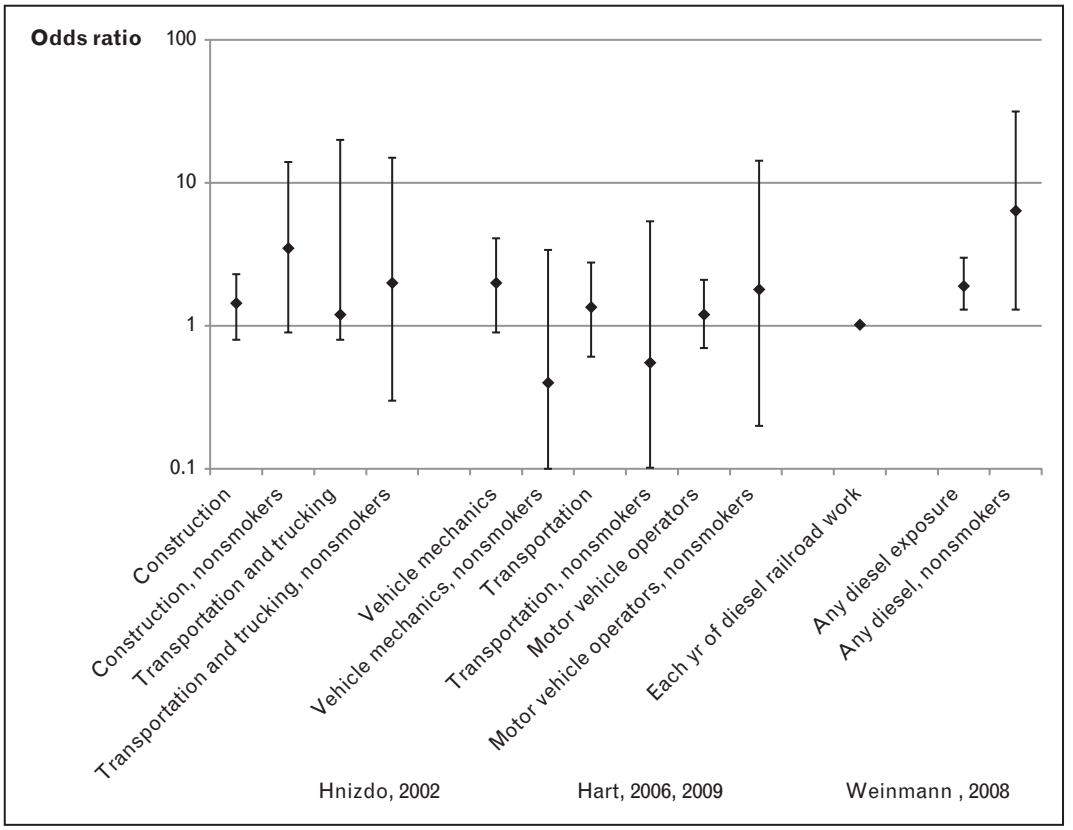

FIGURE 1. Chronic obstructive pulmonary disease odds ratios and 95% confidence intervals for various occupational diesel exhaust exposures.

Thoracic Society in 2003 [27] and again in 2010 [28▪]. In both cases, they concluded that occupational exposures were important risk factors for COPD. Diesel exhaust may be one of the fumes being referred to; however, this specificity is often not available.

Five recent studies have examined the effects of general occupational gas, dust, or fume exposure. In a US population-based case–control study, two methods were used to assess the exposure to vapors, gases, dust, and fumes: a question asking specifically if each job involved exposure to any of these four entities, and a job exposure matrix (JEM) based on an occupational history and expert review [29]. The OR for COPD with self-reported exposure was 2.1 (95% CI 1.4–3.0) and with high likelihood of exposure from the JEM was 1.2 (95% CI 0.6–2.3), after adjustment for age, sex, race/ethnicity, and smoking status.

In a South-African, hospital-based, case–control study, exposure to dust, gas, and fume exposure was determined from both self-reports and a JEM derived from occupational histories taken from each participant [30▪]. After adjustment for age, sex, smoking status, and history of tuberculosis, self-reported chemical, gas, and fume exposure years were associated with an OR of 2.9 (95% CI 1.3–6.3) for low exposure and 3.6 (95% CI 1.6–7.9) for high exposure. The equivalent measures from the JEM were associated with an OR of 2.2 (95% CI 1.1–4.7) for low exposure and 1.8 (95% CI 0.8–3.9) for high exposure.

Risk factors for COPD were examined among 4291 never-smokers participating in Burden of Obstructive Lung Disease (BOLD) from 14 different countries [31▪]. As part of the standardized questionnaire, participants were asked if they had worked for longer than 3 months in a list of occupations previously associated with risk of COPD (for gases/fumes/vapors: welding, fire fighting, chemical or plastic manufacturing, public transportation, or dry cleaning). In multivariable models, 10 or more years of work in a job with gas/fume/vapor exposure was associated with an OR of 1.54 (95% CI 0.71–3.34) in men and no association in women.

In a population-based study in the north of England, questionnaires were sent to a randomly selected subsample of the population [32▪]. The questionnaire specifically asked if each individual had prior occupational exposure to a variety of substances, including asbestos, welding, and dust/fumes. Among respondents who also underwent lung function testing, any occupational exposure was associated with an OR of 3.0 (95% CI 1.3–6.9),

adjusted for age, sex, hay fever, cigarette smoking, and the interaction between sex and occupational exposures.

Among a series of 185 male patients with COPD at a large hospital in Spain, information was obtained on employment status and lifetime occupational history [33]. A JEM was constructed to determine the levels (none, low, and high) of three exposures, biological dust, mineral dust, and gases/fumes. Among those with any work ever in a job with a high level of gas/fume exposure, the relative risk (RR) of having an FEV1 less than 30% predicted (compared to >70% predicted) was 11.4 (95% CI 1.4–95.0), and each additional 10 years of work in such a job was associated with a RR of 1.9 (95% CI 1.0–3.7).

CONCLUSION

The available literature directly examining the effects of occupational diesel exhaust on risk of COPD is quite small. However, these investigations, along with a large body of literature exploring general occupational exposures to dust and fumes, suggest a role of occupational diesel exhaust exposure on risk of COPD. Additional research, with more advanced exposure metrics, is needed to fully elucidate this association.

ABSTRACT

Objectives Evidence from general population-based studies and occupational cohorts has identified air pollution from mobile sources as a risk factor for cardiovascular disease. In a cohort of US trucking industry workers, with regular exposure to vehicle exhaust, the authors previously observed elevated standardised mortality ratios for ischaemic heart disease (IHD) compared with members of the general US population. Therefore, the authors examined the association of increasing years of work in jobs with vehicle exhaust exposure and IHD mortality within the cohort.

Methods The authors calculated years of work in eight job groups for 30 758 workers using work records from four nationwide companies. Proportional hazard regression was used to examine relationships between IHD mortality, 1985–2000, and employment duration in each job group.

Results HRs for at least 1 year of work in each job were elevated for dockworkers, long haul drivers, pick-up and delivery drivers, combination workers, hostlers, and shop workers. There was a suggestion of an increased risk of IHD mortality with increasing years of work as a long haul driver, pick-up and delivery driver, combination worker, and dockworker.

Conclusion These results suggest an elevated risk of IHD mortality in workers with a previous history of regular exposure to vehicle exhaust.

What this paper adds

- Occupational studies of professional drivers, conducted mainly in Denmark and Sweden, have identified elevations in ischaemic heart disease in this occupational group.
- The results of this study suggest that workers in the US trucking industry with a variety of patterns of exposure to vehicle exhaust are at an increased risk of mortality from ischaemic heart disease and that this risk may increase with increasing years of work.

INTRODUCTION

There is growing evidence from population-based studies that fine particulate air pollution is a risk factor for cardiovascular disease.[1–5] The specific constituents responsible are currently not known; however, attention has focused on the importance of particles from motor vehicles that fall mostly within the fine (<2.5 microns in diameter—$PM_{2.5}$) range.[6] There is also suggestive evidence from occupational studies that professional drivers, a group with regular exposure to particulate matter (PM) from mobile sources, have an elevated risk of cardiovascular disease.[7–12] These occupational studies have mainly been conducted in Denmark and Sweden with exposure based on occupation reported in central registers or by self-report. Detailed occupational records in a large cohort of workers with regular exposure to traffic-related PM have not been available.

In a large US cohort of trucking industry workers, we have previously identified elevated standardised mortality ratios (SMR) for ischaemic heart disease (IHD) mortality (SMR=1.41; 95% CI 1.33 to 1.49) compared with the general US population.[13] We also found that, independent of occupational exposures, ambient long-term exposures to PM_{10}, NO_2 and SO_2 at the last known home address were associated with an increased risk of IHD mortality in this cohort.[14] In this industry, job and specific exposure-related duties have remained stable over time and the dates of diesel and other equipment usage are known.[15] An industrial hygiene job review was conducted to identify specific jobs and job duties in the industry and the use of diesel and non-diesel vehicles, and we conducted a national exposure assessment to characterise occupational exposures by job title.[16–20] Each company has provided us with detailed monthly work records for each individual. Thus, we have the unique opportunity to examine the effects of years of work in specific job titles within the industry on IHD mortality while controlling for ambient pollution exposures.

METHODS

Population

Details of the cohort are provided elsewhere.[13 21] Briefly, we obtained detailed computerised work records for unionised employees working in 1985 (54 319 men and 4007 women) from four large national companies. We used National Death Index record axis data, 1985–2000, that lists both underlying and contributing causes of death and identified all deaths with IHD (ICD-9410–414.9; ICD-10 I20–I25.9) listed. We also considered sensitivity analyses restricting to only those cases identified as the underlying cause of death. We limited

analyses to men with at least 1 year of work in a trucking industry job (n=52 836) who also had ambient pollution information available (n=52 345) at their home address. Job title and duties are the same across companies, and the work records included start date, retirement and layoff dates. This allowed us to calculate years of work in each specific trucking industry job group for each employee. Study approval was obtained from the Institutional Review Boards of Brigham and Women's Hospital, Harvard School of Public Health and VA Boston Healthcare System.

Exposure assessment

We categorised exposure into eight job categories based on a review of job titles and duties from a 2001 to 2005 industrial hygiene exposure assessment[16–18] and information on the historical use of diesel and other vehicles by workers in the cohort.[15] The number of workers in each job in 1985 is summarised in table 1. Long haul drivers deliver freight from one large trucking terminal to another and are often away from home for up to 3 days. Pick-up and delivery drivers bring freight to and from customers in the surrounding area and the loading dock. Dockworkers move freight from one truck to another on the loading dock, primarily using propane-powered forklifts, while hostlers move trucks and trailers in the terminal yards. Combination workers perform the duties of a dockworker and of a pick-up and delivery driver as needed on a daily basis. Shop workers perform maintenance on tractors and trailers. Office workers (mostly clerks, managers and salespeople) spend the majority of their work time in an office environment. Each worker could potentially accumulate exposure in each job category throughout his career.

Table 1 Characteristics of the study population (N=52 345)

Characteristic	
	Mean±SD
Age in 1985	42.3±9.9
Year of Hire	1975±7.9

Statistical methods

Proportional hazard regression was used to examine relationships between IHD mortality and employment duration in each trucking industry job category. All eight job-specific exposure variables were included in regression models to adjust for different jobs held throughout a worker's career. Penalised splines[22] were used to test for non-linearity in mortality risk with employment duration, and the change in HR and 95% CIs associated with each year of work was calculated. To closely adjust for age and secular trends, risk sets were generated using attained age in 1-year increments as the time scale. As individuals starting work at one of the participating companies at different ages and different time periods may have different baseline risks of IHD and that these risks will change with calendar time, we created separate baseline hazards based on categories of age in 1985 (<40, 40–49, 50–59, 60–69, 70+), calendar year and decade of hire. Race, census region of residence (based on last home address) and company were considered as potential confounders in the regression models. To control for long-term ambient pollution exposures, we included the average (1985–2000) PM_{10}, NO_2 and SO_2 pollution predicted at the last known address of each employee using national exposure models, we previously developed based on data from EPA monitors.[23] Time-varying variables for years employed and years off work were used to adjust for a healthy worker survivor effect. All analyses were performed in UNIX SAS 9.2 or R 2.4.1.

Indirect adjustment for cigarette smoking

Information on cigarette smoking is not available from the company personnel databases. However, to assess job-related variation in smoking habits, in 2003, a questionnaire was mailed to a sample of 11 986 active and recently retired workers from the same companies as the cohort members.[24] The response rate was 40.5%, and distributions of job titles, gender, region of residence, number of employees at the workplace and urban or rural work location among responders and non-responders were similar. We have previously shown that in logistic regression models adjusted for age, region of the country, educational status, and size and location of the workplace, long haul drivers had higher odds of being ever-smokers compared with other job groups, and pick-up and delivery drivers were less likely to be current smokers. To indirectly adjust for smoking, proportions of current, former and never-smokers among male questionnaire respondents for each job group were used to weight cigarette smoking literature-based fatal IHD RRs for US men (current smoker RR=2.4; former smoker RR=1.1[25]). A job-specific smoking adjustment factor was calculated by dividing the weighted risk for workers employed in each job by the weighted risk for workers not employed in that job,[26 27] and 95% CIs were calculated by considering sampling error in calculating the adjustment factors.[28]

RESULTS

Characteristics of the analysis cohort are presented in table 1. The average age in 1985 was 42 years old, and most workers were hired after long haul trucks changed from gasoline to diesel during the 1950s to 1960s but before or during the transition of pick-up and delivery trucks from gasoline to diesel during the 1970s to 1980s. The workers were predominantly

Downloaded from http://oem.bmj.com/ on October 25, 2017 - Published by group.bmj.com

Caucasian and lived in the South or Midwest. The largest group of workers worked as long haul drivers in 1985, followed by pick-up and delivery drivers, dockworkers and combination workers. There were smaller numbers of hostlers, shop workers, office workers and people in other jobs (managers, trainees, etc).

There were 1357 deaths from IHD (1094 as the underlying cause of death) during the follow-up period (1985–2000). HRs for IHD mortality associated with at least 1 year of work in each specific job category are presented in table 2. There was little difference between the basic, healthy worker survivor effect-adjusted and multivariate models. HRs were statistically significantly elevated for dockworkers and long haul drivers and were elevated for pick-up and delivery drivers, combination workers, hostlers and shop workers. The multivariate HR for clerks was 0.63.

Per cent change in the HR per additional year of work was calculated for long haul drivers, pick-up and delivery drivers, dockworkers and combination workers, the four job titles with the largest number of cases (table 3). Based on the penalised splines (figure 1), the association of IHD with increasing years of exposure was not statistically significantly different from linear in any of these job categories. In linear models, there was a suggestive positive association between increasing years of work in each of these four jobs and an increased risk of IHD mortality. Results were similar for models restricted to those IHD cases listed only as the underlying cause of death.

The job-specific coefficients from the regression models in table 3 were used to estimate HRs for 20 years of work. The job-specific smoking adjustment factors were used to estimate smoking-adjusted risks by dividing each job-specific regression coefficient by the appropriate adjustment factor. After the indirect smoking adjustment, the HRs did not appreciably change in any of the job groups.

DISCUSSION

Within this population of US trucking industry employees, jobs associated with exposures to vehicle exhaust were associated with increases in IHD mortality. Increasing years of work were associated with increases in IHD mortality, although these increases were not statistically significant. These exposures were robust to adjustment for residential ambient average PM_{10}, NO_2 and SO_2 pollution and indirect adjustments for cigarette smoking. Clerks, who did not work in a job with regular exposure to vehicle exhaust, had a decreased risk of dying of IHD. Our findings of elevated risks in the specific job titles are consistent with our earlier SMR analysis comparing this population with members of the general US population (SMRs: ever driver=1.49 (95% CI 1.40 to 1.59), ever dockworker=1.32 (95% CI 1.15 to 1.52), ever mechanic=1.34 (95% CI 1.05 to 1.72)).

Other studies have reported elevated risks of cardiovascular disease in professional drivers, an occupational group with regular exposure to PM from mobile sources, although not all studies have reported elevated risks.[7–11] In Danish bus, taxi and truck drivers, rates of hospital admissions for IHD were consistently elevated in successive 5-year cohorts of 20–59-year-old men studied between 1981 and 1997. Compared with rates in other employed Danish men, the risk was significantly increased, 20%–80%.[11] Gustavsson *et al*[29] found a significantly elevated risk of myocardial infarction among 691 long-distance truck drivers in five counties in Sweden (RR=1.31). The risk was not elevated among short-distance truck drivers, but relatively few (only 169) were included in the study. In a later case–control study assessing cardiovascular risk factors in survivors of first-time myocardial infarction ages 45–70 in Stockholm County between 1992 and 1994, Gustavsson *et al*[30] used a job-exposure matrix to estimate vehicle exhaust exposure intensity and duration. Adjusting for gender, smoking, diabetes and body mass index, the risk associated with greater exposure levels was 1.2–1.3. In a similar analysis in the same cohort, but based on job title, male bus and taxi drivers who worked for >1 year had a non-statistically significantly elevated risk (RR=1.49 95% CI 0.90 to 2.45 and RR=1.34, 95% CI 0.82 to 2.19, respectively). The risk among truck drivers was 1.10, 95% CI 0.79 to 1.53.[31]

Current research efforts suggest that exposure to PM from mobile sources is responsible for adverse cardiovascular events in the general population as well. A prospective study of 4466 participants followed for 8 years in the Netherlands concluded that long-term exposure to traffic-related particulate air pollution measured by ambient Black Smoke measurements, an indicator of elemental carbon (EC), presumably from gasoline and diesel-powered vehicles, was associated with increased all-cause mortality (RR=1.32, 95% CI 0.98 to 1.78) and specifically cardiopulmonary mortality (RR=1.71, 95% CI 1.10 to 2.67) for each 10 $\mu g/m^3$ increase in Black Smoke.[32] An analysis based on specific elements from particles in six US cities found greater effects on daily mortality rates (particularly for cardiovascular deaths) attributable to particles from mobile sources than to particles from other sources.[33] Death from cardiovascular disease in Western European cities has been associated with daily ambient concentrations of Black Smoke.[34]

Table 2 IHD mortality HRs and 95% CIs associated with any work in each major job title, follow-up 1985–2000

Job title	Person years	IHDs	Basic, HR (95% CI)*	HWSE, adjusted HR (95% CI)†	Multivariate, HR (95% CI)‡
Long haul	216 019	626	1.39 (1.18 to 1.64)	1.41 (1.19 to 1.66)	1.44 (1.22 to 1.70)
Pick-up and delivery	228 961	369	1.11 (0.96 to 1.28)	1.09 (0.95 to 1.26)	1.11 (0.96 to 1.28)
Dockworker	295 369	352	1.31 (1.13 to 1.52)	1.30 (1.12 to 1.51)	1.30 (1.12 to 1.51)
Combination	165 151	201	1.07 (0.90 to 1.28)	1.11 (0.93 to 1.33)	1.11 (0.93 to 1.32)
Mechanic	46 524	76	1.05 (0.80 to 1.38)	1.07 (0.82 to 1.41)	1.10 (0.84 to 1.44)
Hostler	58 833	56	1.01 (0.77 to 1.33)	1.06 (0.80 to 1.39)	1.04 (0.79 to 1.37)
Clerk	78 531	31	0.60 (0.41 to 0.87)	0.61 (0.42 to 0.89)	0.63 (0.43 to 0.91)

Each worker could potentially accumulate exposure in multiple job categories throughout his career.
*Basic HRs using regression coefficients from Cox proportional hazards regression models stratified on age in 1985, decade of hire and calendar time, with risk sets by attained age, and adjusted for race.
†HWSE HRs additionally adjusted for the healthy worker survivor effect (total years on work, years off of work).
‡Multivariate HRs additionally adjusted for Census region and the 1985–2000 average ambient PM_{10}, NO_2 and SO_2 values at the last known residential address.
HWSE, healthy worker survivor effect; IHD, ischaemic heart disease.

Table 3 IHD HRs and 95% CIs associated with cumulative years of work in each major job title

Job title	Person years	IHDs	% Change in RR per year of work	Smoking adjustment factor*	HR for 20 yrs of work	
					Multivariate†	Smoking adjusted‡
Long haul	216 019	626	4.2 (−0.9 to 9.8)	1.04	2.32 (0.84 to 6.44)	2.23 (0.80 to 6.18)
Pick-up and delivery	228 961	369	3.7 (−1.4 to 9.2)	0.92	2.09 (0.75 to 5.82)	2.27 (0.81 to 6.32)
Dockworker	295 369	352	3.9 (−1.2 to 9.5)	1.04	2.20 (0.79 to 6.13)	2.11 (0.76 to 5.89)
Combination	165 151	201	3.2 (−2.0 to 8.7)	0.98	1.89 (0.67 to 5.30)	1.93 (0.68 to 5.42)

Each worker could potentially accumulate exposure in multiple job categories throughout his career.
*Job-specific smoking adjustment factors were calculated by dividing the smoking weighted risk for each job by the smoking weighted risk for workers not employed in that job.
†Multivariate HRs using regression coefficients from Cox proportional hazards regression models stratified on age in 1985, decade of hire and calendar time, with risk sets by attained age, adjusted for the healthy worker survivor effect (total years on work, years off of work) race, Census region of residence and the 1985–2000 average ambient PM_{10}, NO_2 and SO_2 values at the last known residential address.
‡Smoking-adjusted HRs are calculated by dividing the multivariate HR by the appropriate smoking adjustment factor. The 95% CIs were calculated by considering the sampling error in calculating each job-specific correction factor.
IHD, ischaemic heart disease.

PM from mobile sources has also been associated with non-fatal cardiovascular disease and systemic markers associated with a greater disease risk. The increased risk of cardiovascular hospitalisation associated with a fixed increment in recent exposure to ambient particles has been shown to increase with the per cent of the particles emitted from traffic sources.[35] In a US Medicare cohort examining the constituents of $PM_{2.5}$, one of the strongest associations was observed between EC and cardiovascular admissions.[36] Findings from Peters *et al*[37] also supported a more specific role for traffic-related particles in cardiovascular damage. In a Boston-based cohort of subjects wearing implantable defibrillators EC and nitrogen dioxide (NO_2) (markers of traffic exposure) were stronger predictors of defibrillator discharge than $PM_{2.5}$. Similarly, in a London study, Black Smoke and NO_2 showed stronger associations with plasma fibrinogen—an intermediate marker of cardiovascular disease risk—than particulate matter <10 microns in diameter (PM_{10}).[38] Peters *et al*[39] found that exposure to traffic was associated with the time of onset of myocardial infarction. In a study of state police troopers riding in their patrol cars, in-vehicle PM (presumably from traffic sources) was associated with elevations in C reactive protein and changes in heart rate variability.[40] In a design similar to our current study, but based in the general population, residents living closer to traffic had a greater risk of incident coronary heart disease, adjusting for residential background air pollution.[41] These observations indicate

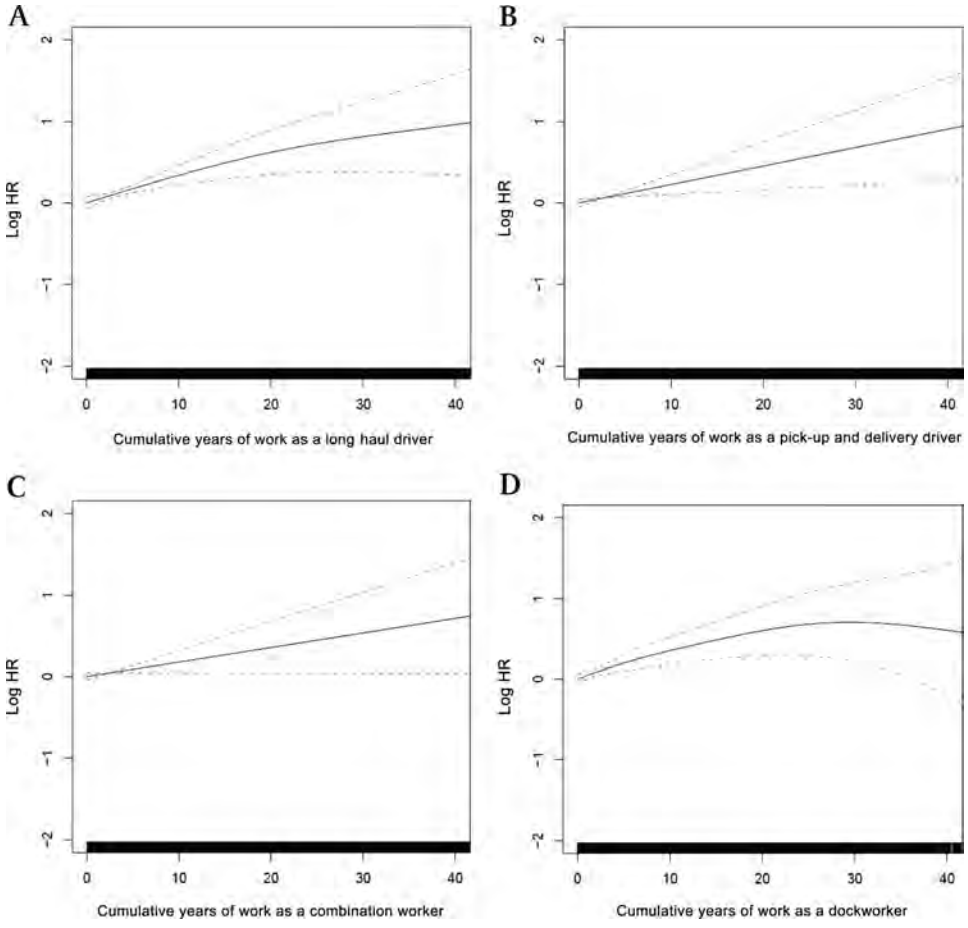

Figure 1 Natural log of the HR and 95% CIs for ischaemic heart disease mortality risk for cumulative years of work as a (A) long haul driver, (B) pick-up and delivery driver, (C) dockworker and (D) combination worker. The solid lines indicate the natural log of the HR, and the dotted lines are the 95% CIs. A histogram of the distribution of years of work is at the bottom of each graph.

Downloaded from http://oem.bmj.com/ on October 25, 2017 - Published by group.bmj.com

that exposure to fine particles from traffic can influence the occurrence of clinical IHD and in some studies, systemic markers of inflammation.

Recent studies have assessed the mechanism responsible for the association of cardiovascular disease mortality with traffic-related exposures. Traffic exposures may specifically adversely affect future IHD by accelerating systemic atherosclerosis (and presumably coronary atherosclerosis) assessed based on quantity of aortic calcification,[42] increase in pulse-wave velocity[43] and carotid intima-media thickness.[44 45] Findings in experimental animal models also support the potential for fine particulate air pollution and specifically traffic-related particles to contribute to the progression of atherosclerosis.[46–48]

A limitation of this analysis is the lack of personal information on potential risk factors for IHD. Although cigarette smoking is an important risk factor, the degree that it is a confounder in this study depends on differences in smoking behaviour associated with job title within the cohort. To minimise the possible effect of uncontrolled confounding by smoking, we have studied workers of similar socioeconomic class, a known correlate of smoking habits.[49 50] Although we were unable to directly survey workers in this cohort, using a representative sample of active and retired workers in the industry,[24] we found that variation in IHD risk among exposed workers did not reflect differences in smoking rates and adjustment did not significantly influence the observed results. As expected,[51] we found that smoking rates in the survey varied by age and birth cohort.[13] Although a limitation of this indirect adjustment is that smoking patterns between jobs may have been different historically, we found that birth-cohort-specific smoking rates were similar among drivers and non-drivers,[13] suggesting that smoking rates did not vary substantially between jobs. In addition, all analyses are tightly controlled for age and calendar year. However, it is still possible that residual confounding by smoking exists. In addition, we do not have information on other important potential confounders, such as physical activity, diet, alcohol consumption, family history, medication use, etc, which, if also related to job title could partially explain our results. Other job-related factors, such as stress, noise, personal work practices, in addition to or instead of traffic pollution exposures may also explain our results. Without direct information on each of these factors, we are unable to definitely determine the precise factors of these job titles responsible for the elevated risk of IHD.

To conclude, our results suggest that IHD mortality in workers with a previous history of regular exposures to vehicle exhaust is elevated and that this risk may increase with increasing exposure duration.

Background Most studies of the association between diesel exhaust exposure and lung cancer suggest a modest, but consistent, increased risk. However, to our knowledge, no study to date has had quantitative data on historical diesel exposure coupled with adequate sample size to evaluate the exposure–response relationship between diesel exhaust and lung cancer. Our purpose was to evaluate the relationship between quantitative estimates of exposure to diesel exhaust and lung cancer mortality after adjustment for smoking and other potential confounders.

Methods We conducted a nested case–control study in a cohort of 12315 workers in eight non-metal mining facilities, which included 198 lung cancer deaths and 562 incidence density–sampled control subjects. For each case subject, we selected up to four control subjects, individually matched on mining facility, sex, race/ethnicity, and birth year (within 5 years), from all workers who were alive before the day the case subject died. We estimated diesel exhaust exposure, represented by respirable elemental carbon (REC), by job and year, for each subject, based on an extensive retrospective exposure assessment at each mining facility. We conducted both categorical and continuous regression analyses adjusted for cigarette smoking and other potential confounding variables (eg, history of employment in high-risk occupations for lung cancer and a history of respiratory disease) to estimate odds ratios (ORs) and 95% confidence intervals (CIs). Analyses were both unlagged and lagged to exclude recent exposure such as that occurring in the 15 years directly before the date of death (case subjects)/reference date (control subjects). All statistical tests were two-sided.

Results We observed statistically significant increasing trends in lung cancer risk with increasing cumulative REC and average REC intensity. Cumulative REC, lagged 15 years, yielded a statistically significant positive gradient in lung cancer risk overall (P_{trend} = .001); among heavily exposed workers (ie, above the median of the top quartile [REC $\geq$ 1005 μg/m^3-y]), risk was approximately three times greater (OR = 3.20, 95% CI = 1.33 to 7.69) than that among workers in the lowest quartile of exposure. Among never smokers, odd ratios were 1.0, 1.47 (95% CI = 0.29 to 7.50), and 7.30 (95% CI = 1.46 to 36.57) for workers with 15-year lagged cumulative REC tertiles of less than 8, 8 to less than 304, and 304 μg/m^3-y or more, respectively. We also observed an interaction between smoking and 15-year lagged cumulative REC ($P_{interaction}$ = .086) such that the effect of each of these exposures was attenuated in the presence of high levels of the other.

Conclusion Our findings provide further evidence that diesel exhaust exposure may cause lung cancer in humans and may represent a potential public health burden.

J Natl Cancer Inst 2012;104:855–868

The question of whether diesel exhaust causes lung cancer in humans has been investigated in many studies since the 1980s. In 1989, the International Agency for Research on Cancer (IARC) classified diesel exhaust as a "probable" carcinogen (IARC classification: Group 2A) based on "sufficient" experimental evidence and "limited" evidence of carcinogenicity in humans (1). Two meta-analyses (2,3) of epidemiological studies have estimated the summary relative risk for lung cancer for those ever occupationally exposed to diesel exhaust as 1.33 (95% confidence interval [CI] = 1.24 to 1.44) (2) and 1.47 (95% CI = 1.29 to 1.67) (3), based on more than 35 studies. A pooled analysis (4) of 13 304 case subjects and 16 282 control subjects from 11 lung cancer case–control studies in Europe and Canada yielded an odds ratio (OR) of 1.31 (95% CI = 1.19 to 1.43) for subjects in the highest vs lowest quartile of cumulative diesel exposure based on a job exposure matrix (4). Although these meta-analyses (2,3) and the pooled analysis (4) suggest a modest but consistent effect, the excesses are in a range that could be explained by confounding (5), particularly from

CONTEXTS AND CAVEATS

Prior knowledge

Most previous studies have found a modest association between the risk of lung cancer and exposure to diesel exhaust (DE). However, these studies typically have inferred DE exposure from job title in the absence of quantitative data on historical DE exposures.

Study design

A nested case–control study of lung cancer and DE in a cohort of 12 315 workers in eight non-metal mining facilities included 198 lung cancer deaths and 562 control subjects. The case–control study evaluated the exposure–response relationship between DE and lung cancer mortality after adjustment for cigarette smoking and other potential confounding factors that were unavailable in the cohort study.

Contribution

The results showed a strong and consistent relationship between quantitative exposure to DE and increased risk of dying from lung cancer. Among heavily exposed workers, the risk of dying from lung cancer was approximately three times greater than that among workers in the lowest quartile of exposure.

Implication

Exposure to DE may cause lung cancer in mine workers.

Limitations

Data on smoking and other potential confounders were derived mainly from next-of-kin interviews. Retrospective assessment of DE exposure may result in some misclassification, leading to imprecision in exposure estimates.

From the Editors

smoking. Alternatively, these excesses may be underestimates of risk due to inadequate latent period for the development of lung cancer in some studies or misclassification of exposure because most epidemiological studies inferred diesel exhaust exposure from job title in the absence of any additional information on level of diesel exposure. In-depth studies of truck drivers (6,7) and railroad workers (8), two occupational groups with light to moderate exposure to diesel exhaust, have found nearly a doubling of lung cancer risk among long-term workers. Retrospective exposure assessments in these studies, however, were hampered by limited historical industrial hygiene measurements. In fact, few studies have based estimates of lung cancer risk on quantitative estimates of exposure to diesel exhaust (8–11). Only one study of German potash miners reported results based on quantitative estimates of historical exposures that included industrial hygiene measurements but was based on only 61 lung cancer deaths (11). To our knowledge, no study to date has had quantitative data on historical diesel exposure coupled with adequate sample size to evaluate the exposure–response relationship for diesel exhaust and lung cancer with adjustment for potential confounding from cigarette smoking and other risk factors for lung cancer.

We conducted a cohort mortality study among workers employed at eight underground non-metal mining facilities (12) and a companion case–control study of lung cancer nested in this cohort to evaluate the risk of lung cancer from exposure to diesel exhaust (The Diesel Exhaust in Miners Study [DEMS]). The purpose of the case–control study reported in this article was to further evaluate the exposure–response relationship between diesel exhaust and lung cancer mortality after adjustment for cigarette smoking and other potential confounding factors that were unavailable in the cohort study.

Materials and Methods

Cohort Design and Follow Up

Eight non-metal mining facilities (three potash, three trona, one limestone, and one salt [halite]) were selected from all US non-metal mining facilities with at least 50 employees who were considered to have had high air levels of diesel exhaust underground but low levels of potential occupational confounders (ie, radon, silica, asbestos) (12). Eligible subjects included all workers who were ever employed in a blue-collar job for at least 1 year after introduction of diesel equipment into the mining facility (year of introduction: 1947–1967 across the eight facilities) until the end of follow-up on December 31, 1997. The cohort consisted of 12 315 workers with a total of 278 041 person-years of follow-up. More detailed information on the cohort can be found in the accompanying article on the cohort study (12).

Case Subject Definition and Identification

Vital status of each cohort member was ascertained through December 31, 1997, by linkage with the National Death Index Plus (NDI Plus) (http://www.cdc.gov/nchs/ndi.htm) and Social Security Administration mortality files. Cause of death information was obtained from NDI Plus or from death certificates (for deaths occurring before the introduction of NDI Plus). A total of 217 deaths were identified with lung cancer (*International Classification of Diseases-O* code 162) specified as either the underlying or contributing cause on the death certificate. We attempted to retrieve pathology reports and diagnostic slides for all case subjects, which proved to be challenging because 85% of the case subjects had died more than 10 years before we contacted the hospital. After repeated attempts, we successfully obtained pathology reports or slides for 70 of the 170 case subjects for whom we obtained consent to access medical records. When the pathology report or diagnostic slides were available, the diagnosis of lung cancer was confirmed through review by an expert pathologist (W. D. Travis), which resulted in the exclusion of one case subject as "unlikely" to have had lung cancer. Of the 217 eligible case subjects identified, we interviewed 213 (98.1%) of their next of kin.

Control Subject Selection for the Nested Case–Control Study

Based on incidence density sampling, we selected up to four control subjects for each lung cancer case subject by random sampling from all members of the study cohort who were alive before the day the case subject died. With this design, all cohort members were eligible to serve as control subjects for more than one case subject, and case subjects before death were eligible to serve as control subjects for other case subjects who died earlier (23 control subjects went on to become case subjects at a later point in time).

Control subjects were individually matched to each case subject on mining facility, sex, race/ethnicity (ie, white, African American, American Indian, Hispanic), and birth year (within 5 years). In the analysis, estimates of diesel exposure and potential confounders (eg, cigarette smoking, employment in other high-risk occupations for lung cancer, and history of nonmalignant respiratory disease) for each control subject were truncated at the date of death of the matched case subject. We identified 650 eligible control subjects and interviewed 611 (94.0%) of them or their next of kin (if the control subject was deceased or too ill for interview). Of the next of kin who were interviewed, 55% were adult children, 31% were spouses or former spouses, 6% were siblings, and 8% were other relatives (with the exception of two friends/co-workers).

The Interview

Living control subjects (n = 222) and next of kin of lung cancer case subjects (n = 198) and ill or deceased control subjects (n = 340) were interviewed using a computer-assisted telephone interview (as explained below, an additional 15 case subjects and 49 control subjects were excluded from analysis). The interview was designed to collect information about the subject's demographics, smoking history (both active and passive), lifetime occupational history, medical history, family medical history, and usual adult diet. We obtained information on all jobs held for 12 months or longer since the age of 16. For each job held at a study mining facility, we collected information on the use of respiratory protective equipment (eg, respirators and masks) and the mining facility location where each subject spent most of his or her time (surface or underground) to supplement information obtained from the subject's company employment record. We also collected information about all jobs held before and after employment at the study mining facilities, including whether the subjects operated or worked near diesel engines.

We compared data obtained from next of kin of deceased control subjects to those obtained from direct interviews with living control subjects for several key variables (eg, cigarette smoking, history of employment in a high-risk occupation for lung cancer, and history of nonmalignant respiratory disease). In general, data obtained from next of kin were similar to those obtained from directly interviewed control subjects. For cigarette smoking, the percentages of direct vs next-of-kin interviews by smoking category were as follows: never smoker, 27% vs 28%; occasional smoker, 3% vs 2%; former smoker of less than one pack per day, 17% vs 17%; former smoker of one to less than two packs per day, 31% vs 24%; former smoker of two or more packs per day, 11% vs 6%; current smoker of less than one pack per day, 1% vs 3%; current smoker of one to less than two packs per day, 9% vs 14%; and current smoker of two or more packs per day, 1% vs 6%, respectively. Living control subjects and next of kin of dead control subjects reported similar proportions of "ever smokers" (73% and 72%, respectively). As expected, deceased control subjects had a slightly higher proportion of current smokers of one or more packs per day than living control subjects (20% and 10%, respectively). This observation is consistent with the reported cause of death; 80% of control subjects who were current smokers of one or more packs per day died of a smoking-related cause compared with 60% of control subjects who never smoked.

This study was approved by the Institutional Review Boards of the National Cancer Institute, the National Institute for Occupational Safety and Health (NIOSH), and Westat, Inc. All interviewees provided verbal informed consent before the interview, and next of kin of case subjects provided written consent to obtain medical records and pathology materials.

Diesel Exhaust Exposure Assessment

The eight facilities in the study had both underground (ore extraction) and surface (ore processing) operations. Underground workers were exposed to diesel exhaust primarily from ore extraction, haulage, and personnel transport vehicles. Surface workers generally had little to no contact with diesel equipment, although some had low levels of diesel exposure from the operation of heavy equipment or diesel trucks or because they worked near diesel equipment.

Respirable elemental carbon (REC), a component of diesel exhaust, is considered the best index of diesel exhaust in underground mining (13). The methods we used to develop quantitative estimates of historical exposure to REC at each mining facility have been described in detail (14–18). Briefly, the exposure assessors (P. A. Stewart, R. Vermeulen, J. B. Coble) developed location- and job title–specific estimates, by year, back to the year of the introduction of diesel equipment in each facility, blinded to mortality outcomes. The estimates were based on measurements from 1998 to 2001 DEMS industrial hygiene surveys at each working mining facility, past Mine Safety and Health Administration enforcement surveys, other measurement data, and information from company records and interviews with long-term workers. The same REC estimates were used to develop quantitative estimates of average intensity and cumulative REC exposure for subjects in both this and the cohort study (12).

A small percentage of subjects in the nested case–control study worked at more than one study facility (ie, 5.9% worked at two facilities and 0.7% worked at three). For these workers, their exposure metrics were based on diesel exposure at all relevant study facilities. Control subjects working in more than one facility were matched to case subjects on the facility where the control subject worked the longest. In facility-specific analyses, workers at multiple facilities were assigned to the facility where they worked the longest.

Statistical Analysis

The effect of diesel exhaust exposure on risk of dying of lung cancer was quantified by the odds ratio. Odds ratios and 95% confidence intervals were estimated by conditional logistic regression. Quartile and tertile cut points for exposure metrics were chosen to achieve approximately equal numbers of case subjects in each category. In all tables, statistical models included a term for exposure (ie, quartiles of average REC intensity [$\mu g/m^3$], cumulative REC exposure [$\mu g/m^3$-y], or duration of exposure [years]). Final models also included terms for potential confounding factors. These included a variable that combined cigarette smoking status and smoking intensity with location worked because initial analyses indicated that the risk of lung cancer from cigarette smoking was different for surface and underground workers (ie, smoking status [never, former, current], by smoking intensity [unknown or

occasional smoker, <1, 1 to <2, ≥2 packs per day], by location [surface only, ever underground]). Former smoker was defined as a case subject who had stopped smoking more than 2 years before their date of death and a control subject who had stopped smoking more than 2 years before the matched case subject's date of death. We included intensity smoked rather than duration smoked or pack-years in our final models; however, results were similar when either of these metrics was used to control for smoking (data not shown). The addition of a variable representing the interaction of location worked and smoking to models statistically significantly improved analogous models that included smoking without location (range of *P* values for the likelihood ratio test = .011–.064 for average REC intensity and cumulative REC, unlagged and lagged). The final models also included two other potential confounders: employment in a high-risk occupation for lung cancer for at least 10 years (ie, miner outside the study mining facilities, truck driver, welder, machinery mechanic, painter) and history of nonmalignant respiratory disease diagnosed at least 5 years before death/reference date (ie, primarily pneumoconiosis, emphysema, chronic obstructive pulmonary disease, silicosis, tuberculosis but excluding asthma, pneumonia, and bronchitis because the latter three diseases were not associated with lung cancer in our study). Other potential confounders [ie, duration of cigar smoking; frequency of pipe smoking; environmental tobacco smoke; family history of lung cancer in a first-degree relative; education; body mass index based on usual adult weight and height; leisure time physical activity; diet; estimated cumulative exposure to radon, asbestos, silica, polycyclic aromatic hydrocarbons (PAHs) from non-diesel sources, and respirable dust in the study facility based on air measurement and other data (14)] were evaluated but not included in the final models because they had little or no impact on odds ratios (ie, inclusion of these factors in the final models changed point estimates for diesel exposure by ≤10%). Exposure levels to other possible confounding exposures in these facilities, such as arsenic, nickel, and cadmium, were not estimated because of very low levels and generally non-detectable measurement results (14).

To test for trend, a Wald test was performed, treating the median value for each level of the categorical exposure variable among the control subjects as continuous in the model. To test for interaction between two risk factors, we added a cross-product term to the logistic model and conducted a likelihood ratio test between the model with and without the cross-product term. All statistical tests were two-sided.

We explored quantitative patterns in odds ratios for both continuous average REC intensity and continuous cumulative REC exposure, denoted by d, by fitting various standard models for occupational epidemiological data, including a log-linear model, $OR(d) = \exp(\beta d)$; a power model, $OR(d) = d^{\beta}$; a linear model, $OR(d) = 1 + \beta d$; and a linear-exponential model, $OR(d) = 1 + \beta d \exp(\gamma d)$. All models were adjusted for the same set of potential confounding factors as described above. We fitted models over the full range of exposure and, for comparative purposes, over a restricted range of lower exposure levels. We compared deviances (a measure of model fit) with the null model that omitted REC exposure, in which larger changes in deviance denoted greater improvements in fit (Supplementary Table 1, available online).

For average REC intensity and cumulative REC exposure, we evaluated lag intervals by excluding exposure occurring 0, 3, . . . , 25 years (by 2-year intervals) before the death/reference date and compared changes in model deviance to a model that omitted REC exposure. The optimal lag interval (ie, the largest improvement in model fit) occurred for a lag between 13–17 years for average REC intensity and 15 years for cumulative REC exposure (Supplementary Figure 1, available online). For consistency, we used a 15-year lag for both exposure metrics in the final analyses.

Of the 213 lung cancer case subjects and 611 control subjects interviewed for study, subjects were excluded for the following reasons: one case subject was identified as "unlikely" to have had lung cancer based on review of pathology material; 10 case subjects did not have any eligible control subjects (because of race/ethnicity for nine nonwhite or Hispanic case subjects and age for one case subject who was 88 years old); 39 control subjects were incorrectly matched on race/ethnicity based on more accurate information obtained during interview; four case subjects and five control subjects were found ineligible for inclusion in the cohort based on a final review of company work histories by NIOSH (12); and five control subjects were not suitable matches to any case subject because the original matched case subject was found to be ineligible for study. The final analytic dataset included 198 case subjects and 562 control subjects (666 control subjects for analytical purposes because some cohort members served as control subjects for more than one case subject). This analytical dataset was predominantly male, with only two female case subjects and eight female control subjects.

Results

Odds ratios for potential confounders (except cigarette smoking) and lung cancer risk are shown in Table 1. A statistically significant increased risk of lung cancer was observed for workers employed at least 10 years in occupations at high-risk for lung cancer (OR = 1.75, 95% CI = 1.06 to 2.91) (Table 1) and those with a history of nonmalignant respiratory disease for at least 5 years before death/reference date (OR = 2.15, 95% CI = 1.21 to 3.82) (Table 1). The elevated risk among those with nonmalignant respiratory disease less than 5 years before death may have been reflective of the early stages of lung cancer. Statistically nonsignificant increased risks were observed for workers who had a family history of lung cancer, smoked cigars for 10 or more years, lived with two or more smokers, exercised less than once per day, and had a vocational school education. Statistically nonsignificant decreased risks were observed among workers who were overweight or obese and who smoked at least 10 pipefuls of tobacco per week (Table 1).

Several non-diesel exposures present at very low levels (ie, levels not typically associated with risk in epidemiological studies) at the study mining facilities were not statistically significantly related to lung cancer risk in our study (Table 1). Levels of radon underground at the study mines were low (ie, arithmetic mean ≤0.02 Working Levels). The odds ratio for workers in the top quartile of cumulative radon exposure was 1.32 (95% CI = 0.76 to 2.29), and workers in quartiles 2 or 3 had little or no increased risk (Table 1). No consistent trend in risk with increasing cumulative radon exposure was apparent (P_{trend} = .220). Little or no

† Adjusted for smoking status/mine location combination (surface work only/never smoker, surface work only/unknown/occasional smoker, surface work only/former smoker/<1 pack per day, surface work only/former smoker/1 to <2 packs per day, surface work only/former smoker/≥2 packs per day, surface work only/current smoker/<1 packs per day, surface work only/current smoker/1 to <2 packs per day, surface work only/current smoker/≥2 packs per day, ever underground work/never smoker, ever underground work/unknown/occasional smoker, ever underground work/former smoker/<1 pack per day, ever underground work/former smoker/1 to <2 packs per day, ever underground work/former smoker/≥ 2 packs per day, ever underground work/current smoker/<1 pack per day, ever underground work/current smoker/1 to <2 packs per day, ever underground work/current smoker/≥2 packs per day).

‡ Other high-risk occupations for lung cancer (ie, miner who worked outside the study mines, truck driver, welder, machinery mechanic, painter).

§ History of respiratory disease excluding asthma, pneumonia, and bronchitis.

‖ Adjusted for cigarette smoking and education.

¶ Pertains only to exposures at study mines.

Quartiles of cumulative radon exposure derived from estimated levels in WL multiplied by months at each job, summed across jobs. Thus, exposure to radon is expressed in units of WLM. One WL = 130 000 MeV alpha energy per liter of air, and one WLM is equivalent to 1 WL exposure for 170 hours.

** Adjusted for smoking status: unknown, never smoker, occasional smoker, former smoker/<1 pack per day, former smoker/1 to <2 packs per day, former smoker/≥2 packs per day, current smoker/<1 pack per day, current smoker/1 to <2 packs per day, current smoker/≥2 packs per day.

†† Quartiles of cumulative exposure derived from intensity scores (0–3) multiplied by years at each job, summed across jobs.

‡‡ Quartiles of cumulative exposure derived from the presence or absence of non-diesel PAHs based on job title tasks (0,1) multiplied by years at each job, summed across jobs.

§§ Respirable dust in milligrams per cubic meter multiplied by years of exposure.

increased risk was observed for possible exposure to asbestos, silica, and PAHs from non-diesel sources, which was consistent with the low measured mean air levels of these potential confounding variables (Table 1) (14). Workers in the top quartile of cumulative respirable dust exposure had an elevated risk (OR = 1.31, 95% CI = 0.70 to 2.46), but workers in quartiles 2 or 3 had no increased risk (Table 1). Factors with statistically nonsignificant increased or decreased risks had little or no confounding effect on estimates of risk from diesel exposure (ie, changed point estimates by ≤10%) and were not included in the final models.

Table 2 shows the effect of cigarette smoking overall and cross-classified by location of employment (ie, surface only and ever underground). Overall, for both surface-only and ever underground workers combined, the risk of lung cancer was statistically significantly associated with smoking status (never, former, current smoker) and smoking intensity (former smoker of ≥2 packs per day vs never smoker: OR = 5.40, 95% CI = 2.23 to 13.06; current smoker of ≥2 packs per day vs never smoker: OR = 12.41, 95% CI = 5.57 to 27.66) (Table 2). We also observed an interaction between cigarette smoking and location of employment, after adjustment for cumulative REC, lagged 15 years ($P_{interaction}$ = .082). The lung cancer risks associated with moderate (1 to <2 packs per day) and heavy smoking (≥2 packs per day) were higher among workers who only worked at the surface than among those who ever worked underground for both current and former smokers. For example, the odds ratio for current smokers of one to less than two packs per day who worked only at the surface was 13.34 (95% CI = 4.50 to 39.53) compared with an OR of 4.51 (95% CI = 1.50 to 13.58) for those who ever worked underground (Table 2). Because the effect of smoking appeared to be diminished among underground workers compared with that among surface workers, we included the cross classification of location of employment, smoking status, and smoking intensity in all models used to estimate lung cancer risk by diesel exposure (Tables 1, 3, and 7; Figure 1), unless noted otherwise. It is also noteworthy that among never smokers, underground and surface-only workers had similar risks after adjustment for 15-year lagged cumulative REC (OR = 0.90; 95% CI = 0.26 to 3.09) (Table 2), suggesting that the risk experienced by surface-only workers was mainly due to smoking.

Table 2. Odds ratios (ORs) and 95% confidence intervals (CIs) for smoking status/smoking intensity by location of employment*

Smoking status/smoking intensity (packs per day)	OR (95% CI), No. of case subjects/No. of control subjects

* REC = respirable elemental carbon.

† ORs relative to never smokers who worked only surface jobs, adjusted for cumulative REC, lagged 15 years (quartiles: 0 to <3 μg/m³-y; 3 to <72 μg/m³-y, 72 to <536 μg/m³-y, ≥536 μg/m³-y), history of respiratory disease 5 or more years before date of death/reference date, and history of a high-risk job for lung cancer for at least 10 years. *P* value for interaction between smoking status and location of employment based on likelihood ratio test = .082.

‡ ORs for intensity smoked relative to never smokers, adjusted for cumulative REC, lagged 15 years (quartiles: 0 to <3 μg/m³-y; 3 to <72 μg/m³-y, 72 to <536 μg/m³-y, ≥536 μg/m³-y), location of employment (surface only, ever underground), history of respiratory disease 5 or more years before date of death/reference date, and history of a high-risk job for lung cancer for at least 10 years.

§ Unknown includes subjects with unknown smoking status, and subjects considered occasional smokers, who smoked at least 100 cigarettes during their lifetimes, but never smoked regularly (≥1 cigarette per day for at least 6 months).

Trends in risk with increasing levels of diesel exposure are either statistically significant or of borderline significance ($P_{trend} \leq .08$) for all metrics (both unlagged and lagged) (Table 3). The strongest gradient in risk was seen for 15-year lagged cumulative REC ($P_{trend} = .001$). The odds ratio for workers in the top quartile of 15-year lagged cumulative REC exposure (ie, ≥536 μg/m³-y) was 2.83 (95% CI = 1.28 to 6.26) compared with workers in the lowest quartile. When the top exposure quartile was split at the median (ie, 1005 μg/m³-y), the risk continued to rise (P_{trend} over all five exposure levels = .002); odds ratios were 2.53 (95% CI = 1.06 to 6.04) and 3.20 (95% CI = 1.33 to 7.69) for workers in the top quartile with cumulative REC exposures below and above the median of the quartile, respectively.

We observed a statistically significant gradient in risk with increasing number of years exposed to diesel exhaust among all workers ($P_{trend} = .043$), although an elevated odds ratio occurred only in the highest duration category. The odds ratio for workers exposed to diesel exhaust for 15 or more years was 2.09 (95% CI = 0.89 to 4.90) compared with surface workers with negligible or bystander exposure (Table 3).

We also examined risk among all subjects who ever worked underground (Table 4) and among those who worked only at the surface (Table 5). Among underground workers, we observed statistically significant trends in risk with increasing average REC intensity, unlagged ($P_{trend} = .01$) and lagged 15 years ($P_{trend} = .001$), and with increasing cumulative REC, lagged 15 years ($P_{trend} = .004$) (Table 4). Among surface workers, in contrast, no consistent positive gradient in risk with increasing diesel exposure was apparent (Table 5), probably due to the small number of subjects (53 case subjects and 100 control subjects) and the low levels of diesel exposure experienced by surface workers. Because of the increased precision gained by estimating odds ratios based on all subjects, our primary estimates of risk are based on surface and underground workers combined (Table 3).

We stratified the combined results (Table 3) on whether the subject had self-reported diesel exhaust exposure from a job outside the study mining facility (eg, ever employed as a long-haul truck driver) (data not shown). No systematic differences in risk were apparent among subjects with or without occupational diesel exposure outside the study facility ($P_{interaction}$ between cumulative REC, lagged 15 years, and outside occupational diesel exhaust exposure = .222).

Use of protective equipment did not appear to modify the observed associations between diesel exhaust exposure and lung cancer. However, most information on protective equipment use was obtained from next-of-kin interviews, resulting in a large number of workers with unknown data (59 case subjects and 129 control subjects). Subjects who reported having used protective equipment appeared to experience risks similar to the estimates for all workers combined (Table 3). For example, among workers who used protective equipment, odds ratios for 15-year lagged cumulative REC exposures of less than 3 μg/m³-y, 3 to less than 72 μg/m³-y, 72 to less than 536 μg/m³-y, and 536 μg/m³-y or more were 1.0 (referent), 0.31 (95% CI = 0.04 to 2.23; 16 case subjects and 42 control subjects), 1.76 (95% CI = 0.11 to 27.91; 10 case subjects and 23 control subjects), and 3.66 (95% CI = 0.26 to 52.09; 20 case subjects and 31 control subjects), respectively.

Figure 1 shows category-specific odd ratios (square symbol), with confidence intervals omitted for clarity, and fitted odds ratios for 15-year lagged average REC intensity and cumulative REC using various continuous models. To provide additional points for graphing the exposure–response curve based on categorical data (Figure 1), we expanded the number of cut points (cut points for average REC intensity, lagged 15 years: <2, 2 to <4, 4 to <8, 8 to <16, 16 to <32, 32 to <64, 64 to <128, 128 to <256, and ≥256 μg/m³; cut points for cumulative REC, lagged 15 years, were similarly defined but multiplied by a factor of 10 to account for duration of exposure: <20, 20 to <40, 40 to <80, 80 to <160, 160 to <320, 320

Table 3. Odds ratios (ORs) and 95% confidence intervals (CIs) for average and cumulative REC and total duration REC exposure*

* *P* values based on two-sided Wald test for linear trend; adjusted for smoking status/mine location combination (surface work only/never smoker, surface work only/unknown/occasional smoker, surface work only/former smoker/<1 pack per day, surface work only/former smoker/1 to <2 packs per day, surface work only/former smoker/≥2 packs per day, surface work only /current smoker/<1 pack per day, surface work only/current smoker/1 to <2 packs per day, surface work only/current smoker/≥2 packs per day, ever underground work/never smoker, ever underground work/unknown/occasional smoker, ever underground work/former smoker/<1 pack per day, ever underground work/former smoker/1 to <2 packs per day, ever underground work/former smoker/≥2 packs per day, ever underground work/current smoker/<1 pack per day, ever underground work/current smoker/1 to <2 packs per day, ever underground work/current smoker/≥2 packs per day); history of respiratory disease 5 or more years before date of death/reference date; and history of a high-risk job for lung cancer for at least 10 years. REC = respirable elemental carbon.

† The number of case subjects in the referent group for the 15-year lagged average REC analysis is 2 fewer than that in the unlagged analysis because rounded cut points are presented. The unrounded cut points are <0.86 and <1.37 μg/m³, respectively.

‡ Unexposed includes all subjects who worked surface jobs with either negligible or bystander exposure to REC, regardless of duration.

to <640, 640 to <1280, 1280 to <2560, and ≥2560 μg/m³-y; Supplementary Table 2, available online). Odds ratios increased with 15-year lagged average REC intensity and leveled off above 20–80 μg/m³ (Figure 1, A for the full range and Figure l, B for average REC intensity under 128 μg/m³). For the full range, the odds ratio pattern was best explained by a one-parameter power model (deviance = 5.3, $P = .022$), whereas for the restricted range, the power and linear models were comparable (deviance = 2.8, $P = .092$ and deviance = 3.2, $P = .075$, respectively). A similar increasing pattern of odds ratios was observed for cumulative REC exposure, lagged 15 years (Figure 1, C for the full range and Figure l, D for cumulative REC under 1280 μg/m³-y), with a leveling off of risk for exposures above 1,000 μg/m³-y and perhaps a decline in risk among the most heavily exposed workers. The two-parameter linear-exponential model (dotted line) was the best fitting model for the full range (relative to the null model, deviance = 12.2, $P = .002$) (Figure l, C); for the restricted range, the best models were the one-parameter linear model (dashed-dotted line) (deviance = 15.6, $P < .001$) and the two-parameter linear-exponential model (dotted line) (deviance = 16.0, $P < .001$) (Figure 1, D) (Supplementary Table 1, available online). We carried out similar model comparisons using the unlagged exposure metrics (Supplementary Table 3, available online). However, our evaluation of optimal lag intervals (Supplementary Figure 1, available online) suggested that the unlagged approach led to exposure misclassification because recent exposures may not have had sufficient time to contribute to lung cancer risk and thus resulted in generally poorer fit of the various models.

The combined effect of diesel exposure and intensity of cigarette smoking is shown in Table 6. Among the 14 case subjects and 178 control subjects who never smoked, odds ratios by tertile of cumulative REC, lagged 15 years, were: 1.0 (referent), OR = 1.47 (95% CI = 0.29 to 7.50), and OR = 7.30 (95% CI = 1.46 to 36.57). Risk also increased with increasing level of diesel exposure among smokers of less than one and one to less than two packs per day. In contrast, risk decreased with increasing levels of diesel exposure among smokers of at least two packs per day. Similarly, risk associated with smoking intensity was modified by diesel exposure. Among workers in the lowest tertile of cumulative REC, lagged 15 years, smokers of at least two packs per day had a risk 27 times that of nonsmokers, whereas among those in the highest tertile of cumulative REC, heavy smokers had about 2.5-fold the risk of nonsmokers. The $P_{interaction}$ between level of diesel exposure and cigarette smoking was .086.

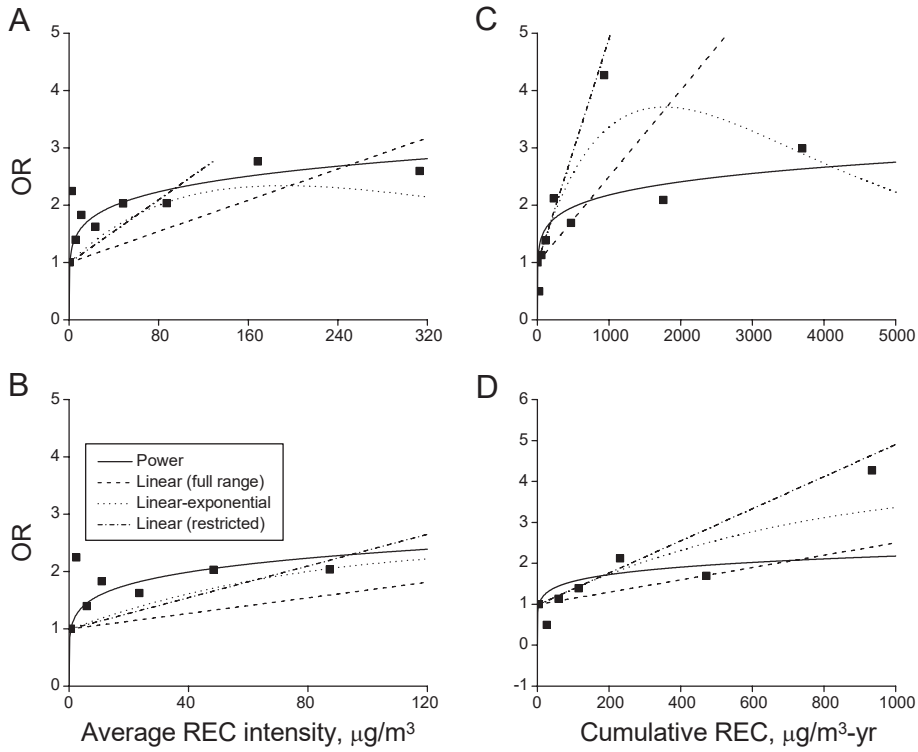

Figure 1. Odds ratios (ORs) (**solid squares**) for lung cancer by expanded categories of average respirable elemental carbon (REC) intensity and cumulative REC (Supplementary Table 2, available online). **A**) Average REC intensity, full range; **B**) Average REC intensity, less than 128 μg/m^3; **C**) Cumulative REC exposure, full range; **D**) Cumulative REC exposure, less than 1280 μg/m^3-y. ORs located at the mean exposure within category. Models for OR by continuous exposure (d) include a power model, $OR(d) = d^{\beta}$ (**solid line**); a linear model, $OR(d) = 1 + \beta\, d$ (**dashed line** for the full range and **dashed-dotted line** for the restricted range); and a linear-exponential model, $OR(d) = 1 + \beta\, d \exp(\gamma\, d)$ (**dotted line**). Exposure variables were based on a 15-year lag. Confidence intervals were omitted for clarity. The log-linear model was excluded because it did not fit the data well.

We evaluated lung cancer risk by quantitative level of diesel exposure for each type of mining facility (Table 7). Too few workers were employed in the one salt and the one limestone mining facility to estimate risk for these types separately. For workers in both potash and trona mining facilities, risk tended to increase with increasing levels of average REC intensity and cumulative REC exposure. Trends were more consistent among potash miners, perhaps reflecting more stability in odds ratios resulting from twice as many case subjects in the potash as in the trona facilities (Table 7).

Discussion

This case–control study nested within a cohort of miners showed a strong and consistent relation between quantitative exposure to diesel exhaust and increased risk of dying of lung cancer. To our knowledge, this is the first report of a statistically significant exposure–response relationship for diesel exposure and lung cancer based on quantitative estimates of historical diesel exposure with adjustment for smoking and other potential confounders. We observed increasing trends in risk with increasing exposure to diesel exhaust for both average REC intensity and cumulative REC exposure, unlagged and lagged 15 years, with the strongest gradient in risk with cumulative REC, lagged 15 years. We further observed a gradient of increasing risk within the top quartile of 15-year lagged cumulative REC exposure for workers below and above the median of the quartile. The associations between diesel exposure and lung cancer were apparent for workers employed in either the potash or trona facilities (too few workers were employed in the one salt and one limestone mine to estimate risk separately). The consistency of findings for both potash and trona facilities is noteworthy because smoking was prohibited in the trona facilities but not in potash or the other facilities in the study. Reports by next of kin or study subjects of workers' use of protective equipment within the study mining facilities and workers' additional occupational exposure to diesel exhaust outside the study facilities had little or no impact on our findings.

These positive findings are consistent with those of the cohort analysis of underground workers in the same study population (12). However, estimates of risk for underground workers in the case–control analysis were somewhat higher than those based on the cohort analysis. For example, the odds ratios by quartile of the 15-year lagged cumulative REC exposure in the case–control analysis were 1.0, 2.11, 3.48, and 5.90 (for cohort cut points, <108, 108 to <445, 445 to <946, and ≥946 μg/m^3-y, respectively), compared with hazard ratios of 1.0, 1.50, 2.17, and 2.21 from the cohort analysis (12). The lower point estimates from the cohort analysis may be partly due to negative confounding from cigarette smoking because current smoking was inversely related to diesel exposure in underground workers (36% and 21% current smokers in lowest vs highest cumulative REC tertile, respectively). Odds ratios for underground workers in the case–control analysis using the same cohort cut points dropped to 1.0, 1.94, 2.42, and 3.75, respectively, when smoking was removed from the model.

The continuous models suggest a steep slope at the low end of the exposure–response curve followed by a leveling, or perhaps even a decline, in risk among the most heavily exposed workers. A plateauing of exposure–response curves has been reported in studies of other occupational exposures and cancer risk (19). Possible biological explanations for a plateauing effect include saturation of metabolic activation and enhanced detoxification or greater DNA repair efficiency at higher exposure levels.

Table 4. Odds ratios (ORs) and 95% confidence intervals (CIs) for average and cumulative REC and total duration REC exposure for subjects who ever worked underground jobs*

* *P* values based on two-sided Wald test for linear trend. Adjusted for smoking status (never smoker, unknown/occasional smoker, former smoker/<1 pack per day, former smoker/1 to <2 packs per day, former smoker/≥2 packs per day, current smoker/<1 pack per day, current smoker/1 to <2 packs per day, current smoker/≥2 packs per day); history of respiratory disease 5 or more years before date of death/reference date; and history of a high-risk job for lung cancer for at least 10 years. REC = respirable elemental carbon.

† Eight case subjects and 148 control subjects were excluded because they no longer belonged to a complete matched set after analysis was restricted to underground workers.

Alternatively, nondifferential misclassification of diesel exposure may be greater at higher exposures, obscuring further increases in risk.

We observed an increased lung cancer risk associated with diesel exposure as was seen among German potash miners (11), as well as among other diesel-exposed occupational groups including truck drivers (6,7), railroad workers (8,20), dockworkers (9), and bus garage workers (10). The German potash miners study (11) found elevated risk with increasing estimated cumulative total carbon exposure (another surrogate for diesel exposure), although the trend was not statistically significant. Relative risks were 1.0, 1.13, 2.47, 1.50, and 2.28 for exposure quintiles (ie, <1.29, 2.04, 2.73, 3.90, >3.90 mg/m³-y, respectively) (11). Some differences between the German study (11) and this study are that this study is considerably larger (US miners: 198 lung cancer deaths out of a total of 278 041 person-years; German miners: 61 lung cancer deaths out of 152 557 person-years), and the US miners had a longer latent period for the development of lung cancer than the German miners because diesel technology was introduced earlier in the US study mines (1947–1967) than in the German mines (1969). Finally, in this study, an intensive effort was undertaken to characterize diesel exposure levels over time by incorporating changes in size of the diesel equipment, numbers of equipment, and air flow rates exhausted from the mines based on information collected from the facilities. Our information indicated that these factors varied considerably over time (14). In the German study, the investigators relied on reports from local engineers and industrial hygienists that working conditions were constant over past years. However, in contrast to this study, no past industrial hygiene measurements were available to confirm this assumption.

We observed an attenuation of the effect of cigarette smoking among study subjects who were exposed to high levels of diesel exhaust as estimated by REC (Table 6). This finding mirrors a recent observation from a study in Xuanwei, China (21), where lung cancer rates are high because of unvented indoor burning of coal for heating and cooking in homes (22). The effect of tobacco on lung cancer risk in that study was weak in the presence of heavy indoor exposures from smoky coal but became stronger with installation of venting, which greatly diminished smoky coal air concentrations (21,22). Little is known about the effect of the interaction between cigarette smoking and diesel exhaust exposure on lung cancer risk. If our observation of attenuation of the smoking effect in the presence of high levels of diesel exhaust is confirmed, several possible mechanistic explanations are apparent. First, at high levels of diesel exhaust exposure, PAHs, nitro-PAHs, and related compounds could compete with the metabolic activation of PAHs in tobacco smoke, leading to enzyme saturation. For example, PAHs in complex mixtures have been shown to have less than additive genotoxic effects at higher exposure levels (23). Second, constituents of diesel exhaust may suppress enzymes that

activate or induce enzymes that detoxify carcinogens in tobacco smoke. For example, diesel exhaust particles have been shown to reduce activity of CYP2B1, which plays a role in the activation of certain tobacco-specific nitrosamines (24). Also, diesel particulate matter has been shown to reduce the initiation of skin tumors in Sencar mice treated with the potent PAH dibenzo[a,l]pyrene, possibly through inhibition of enzymes that carry out its metabolic activation (25).

We also observed a weakening of the diesel exhaust effect among heavy smokers (ie, smokers of at least two packs per day), which is necessarily implied by the observation of a weakening of the effect of smoking at least two packs per day among workers heavily exposed to diesel exhaust. It has previously been reported that coal dust burden in the lungs of coal miners is reduced among smokers, which may be attributable to increased coal dust clearance (26), and it is possible that diesel exhaust particulate deposition may be reduced in the lungs of smokers by a similar process. Although little experimental evidence is available to date to support and explain effect modification of diesel exposure by smoking, it is theoretically possible by one or more of the mechanisms described above.

* *P* values based on two-sided Wald test for linear trend. Adjusted for smoking status/mine location combination (surface work only/never smoker, surface work only/unknown/occasional smoker, surface work only/former smoker/<1 pack per day, surface work only/former smoker/1 to <2 packs per day, surface work only/former smoker/≥2 packs per day, surface work only/current smoker/<1 pack per day, surface work only/current smoker/1 to <2 packs per day, surface work only/current smoker/≥2 packs per day, ever underground work/never smoker, ever underground work/unknown/occasional smoker, ever underground work/former smoker/<1 pack per day, ever underground work/former smoker/1 to <2 packs per day, ever underground work/former smoker/≥2 packs per day, ever underground work/current smoker/<1 pack per day, ever underground work/current smoker/1 to <2 packs per day, ever underground work/current smoker/≥2 packs per day); history of respiratory disease 5 or more years before date of death/reference date; and history of a high-risk job for lung cancer for at least 10 years. REC = respirable elemental carbon.

If the observed interaction between smoking and diesel exhaust represents a real effect, then the generalizability of our estimates of risk for diesel exposure to other populations depends not only on the level of exposure to diesel exhaust but also on the distribution of smoking status and intensity in the population. For example, estimates of lung cancer risk in a population of never smokers with diesel exposures similar to those of the miners in this study would be 1.0, 1.47, and 7.30 for individuals with cumulative REC, lagged 15 years, of less than 8 μg/m^3-y, 8 to less than 304 μg/m^3-y, and 304 μg/m^3-y or more, respectively. In contrast, the overall study population, which included 29% never smokers, had lower odds ratios of 1.0, 1.12, and 2.40 for the same tertiles of cumulative REC exposure, lagged 15 years, respectively (data not shown). In fact, the proportion of never smokers in this study population is substantially lower than the 51% reported for the US population of men aged 18 years or older (27), suggesting that diesel-related estimates of lung cancer risk in the US population may be higher than the overall risk estimates reported here because the proportion of never smokers in the US population is higher than in this study cohort.

Our study has several major strengths including its relatively large size, which provided adequate statistical power to detect a statistically significant exposure–response relationship, adequate latent period for the development of lung cancer, detailed exposure assessment that enabled us to evaluate risk based on quantitative historical exposure to REC, subjects with a wide range of diesel exposure and with underground workers experiencing exposure levels considerably higher than that of other occupationally exposed groups in previous studies, a high interview participation rate for both case subjects and control subjects, and the ability to control for confounding from smoking and other lung cancer risk factors. Two main limitations are also apparent. First, the data on smoking and other potential confounders were derived mainly from next-of-kin interviews. Although a comparison of confounder data derived directly from living and from next of kin for deceased control subjects revealed comparability of responses, we cannot completely rule out the possibility of residual confounding. Second, as in most epidemiological studies of cancer that rely on retrospective exposure assessment, estimates of diesel exposure in this study undoubtedly had some imprecision despite considerable effort to minimize misclassification. This imprecision is likely to result in nondifferential misclassification of exposure, which would tend to bias the estimates of risk toward the null (28). Thus, the true estimates of lung cancer risk associated with diesel exhaust may, in fact, be higher than those reported here.

In sum, our results provide further evidence supporting a causal effect of diesel exhaust exposure on lung cancer mortality in humans. We observed a statistically significant exposure–response relationship after we adjusted for possible confounding from smoking and other established and hypothesized lung cancer risk factors. The exposure–response curve showed a steep increase in risk with increasing exposure at low-to-moderate levels followed by a plateauing or perhaps a decline in risk among heavily exposed subjects.

Our findings are important not only for miners but also for the 1.4 million American workers and the 3 million European workers exposed to diesel exhaust (29), and for urban populations worldwide. Some of the higher average elemental carbon levels reported in cities include Los Angeles (4.0 μg/m^3) (30), the Bronx (a borough in New York City) (6.6 μg/m^3) (31), nine urban sites in China (8.3 μg/m^3) (32), Mexico City (5.8 μg/m^3) (33), and Estarreja, Portugal (11.8 μg/m^3) (34). Environmental exposure to average elemental carbon levels in the 2-6 μg/m^3 range over a lifetime as would be experienced in highly polluted cities approximates cumulative exposures experienced by underground miners with low exposures in our study. Because such workers had at least a 50% increased lung cancer risk, our results suggest that the high air concentrations of elemental carbon reported in some urban areas may confer increased risk of lung cancer. Thus, if the diesel exhaust/lung cancer relation is causal, the public health burden of the carcinogenicity of inhaled diesel exhaust in workers and in populations of urban areas with high levels of diesel exposure may be substantial.

***Rationale*: Diesel motor exhaust is classified by the International Agency for Research on Cancer as probably carcinogenic to humans. The epidemiologic evidence is evaluated as limited because most studies lack adequate control for potential confounders and only a few studies have reported on exposure–response relationships.**

***Objectives*: Investigate lung cancer risk associated with occupational exposure to diesel motor exhaust, while controlling for potential confounders.**

***Methods*: The SYNERGY project pooled information on lifetime work histories and tobacco smoking from 13,304 cases and 16,282 controls from 11 case–control studies conducted in Europe and Canada. A general population job exposure matrix based on ISCO-68 occupational codes, assigning no, low, or high exposure to diesel motor exhaust, was applied to determine level of exposure.**

***Measurements and Main Results*: Odds ratios of lung cancer and 95% confidence intervals were estimated by unconditional logistic regression, adjusted for age, sex, study, ever-employment in an occupation with established lung cancer risk, cigarette pack-years, and time-since-quitting smoking. Cumulative diesel exposure was associated with an increased lung cancer risk highest quartile versus unexposed (odds ratio 1.31; 95% confidence interval, 1.19–1.43), and a significant exposure–response relationship (P value < 0.01). Corresponding effect estimates were similar in workers never employed in occupations with established lung cancer risk, and in women and never-smokers, although not statistically significant.**

***Conclusions*: Our results show a consistent association between occupational exposure to diesel motor exhaust and increased risk of lung cancer. This association is unlikely explained by bias or confounding, which we addressed by adjusted models and subgroup analyses.**

AT A GLANCE COMMENTARY

Scientific Knowledge on the Subject

Diesel motor exhaust is currently classified as a probable lung carcinogen.

What This Study Adds to the Field

Our results from a very large pooled study show a small, consistent association between occupational exposure to diesel motor exhaust and lung cancer, after adjusting for potential confounders, such as smoking and other occupational exposures. The effect is similar for non–small cell and small cell lung carcinoma.

Keywords: epidemiologic studies; lung neoplasm; occupational exposure; vehicle emissions

Diesel motor exhaust (DME) consists of a complex mixture of components in gas or particulate form. The particulates are mainly composed of cores of elemental carbon; traces of metallic compounds; and adsorbed organic materials including aromatic hydrocarbons, polycyclic aromatic hydrocarbons, aldehydes, and nitrogen oxides (1, 2). The composition of DME

has changed over time as a result of improvements in engine technology and type of fuels. The highest levels of occupational DME exposure have been reported among workers engaged in underground mining, tunnel construction, and underground mine maintenance (3).

Regulations for diesel engine emissions were established in the United States in the 1960s (4), and have thereafter been introduced in Europe and around the world (5). The legislative limits for particulate matter in the European Union have until today referred to the particulate matter mass and not the number of particles. Because most of the particles are small in size (<100 nm) the corresponding mass is low and a large number of ultrafine particles may remain even when the legislative limit of mass is respected (6). A particle number limit is planned to be introduced in the EURO 6 legislative limits, due to enter into force from the end of 2012 (7).

Diesel particles are, because of their small size, highly respirable and can penetrate deep into the lungs and so cause temporary exposure-related symptoms, chronic respiratory effects, and probably lung cancer (8). A large number of individual cohort and case–control studies have suggested an association between DME exposure and increased lung cancer risk (9–13). Nevertheless, lack of dose–response within and across occupations, and incomplete adjustment for smoking and other confounders, have not allowed a conclusion regarding the presence of a casual relationship (14, 15).

The International Agency for Research on Cancer (IARC) classified DME as probably carcinogenic to humans (group 2A) in 1989, based on limited evidence in humans and sufficient evidence in experimental animals for whole DME and for extracts of DME particles. For the carcinogenicity of gas-phase DME (with particles removed) in experimental animals the evidence was classified as inadequate (16).

Our objective was to study the association between occupational DME exposure and lung cancer risk by duration and level of exposure, and cumulative dose, in a very large dataset including individual data on occupational history and smoking habits.

Some of the results of this study have been previously reported in the form of abstracts (17, 18).

METHODS

The SYNERGY project represents a pooling of data from 11 lung cancer case–control studies from Europe and Canada where the primary objective is to study joint effects of exposure to concurrent occupational lung carcinogens (asbestos, polycyclic aromatic hydrocarbons, nickel, chromium, and silica) and smoking. The studies included in SYNERGY are well-designed population- or hospital-based case–control studies, and in one case a nested case–control study, that have collected lifetime tobacco history and occupational data. The inclusion of studies in SYNERGY was also determined by the availability of exposure data for the selected agents in respective country or region. The SYNERGY project is coordinated by IARC, the Institute for Prevention and Occupational Medicine of the DGUV (IPA), and the Institute for Risk Assessment Sciences at Utrecht University (IRAS). More information about the SYNERGY project is available (http://synergy.iarc.fr). The present analysis on DME is based on the same pooled studies.

The studies that have contributed data to the present analysis are described in Table 1. In most studies, cases and controls were frequency-matched for variables, such as sex and age. Most interviews (84%) were conducted face to face with the subjects. The LUCAS and LUCA studies were restricted to men and the PARIS study included only regular smokers. MORGEN is a case-control study nested in the prospective EPIC cohort in The Netherlands and the subjects filled in a questionnaire at recruitment. Thus, smoking data and occupational information in the MORGEN study are lacking for the time interval between enrolment and diagnosis or end of follow-up (mean interval 5.3 yr; SD 2.7). Besides MORGEN, all studies have provided data on lifetime smoking habits and complete occupational history. The occupational data were originally mostly coded according to national classifications, and therefore had to be recoded into the International Standard Classification of Occupations (ISCO-68) (19). A conversion table from the Nordic occupational classification (NYK-83) codes to ISCO-68 was created and validated at Karolinska Institute and thereafter applied to the Swedish data. The countries participating in the IARC multicenter study on lung cancer in Central and Eastern Europe and the United Kingdom (INCO) are included as individual studies in these analyses.

Ethical approvals were obtained in accordance with legislation in each country, and in addition by the Institutional Review Board at IARC.

Exposure Assessment

DME exposure was estimated by using a general population job-exposure matrix (DOM-JEM) based on five-digit ISCO-68 codes. The DOM-JEM for DME was created by three occupational exposure experts (H.K., R.V., and S.P.) and assigns scores of no exposure = 0, low = 1, or high = 4 exposure levels of DME to each ISCO code. The assignment of DME exposure to each ISCO code was initially performed independently, and for conflicting scores a consensus was achieved. Initial agreement for the three experts was 92% (20). * Nested case–control study.

1,840 job codes in ISCO-68, 202 (11%; e.g., drivers, engineers, technicians, and farmers) were assigned low DME levels and 27 (1.5%; e.g., miners, mechanics for agricultural machinery and diesel engines, and railway and road vehicle loaders) were assigned high levels of DME exposure (more information about the DOM-JEM is available on request). Linkage of the job histories with the DOM-JEM assigned a DME exposure level to each job period.

We created two indices of DME exposure: duration across all job periods for the two exposure levels (low and high) separately; and an indicator of cumulative dose based on the intensity score (low = 1, high = 4), multiplied by duration for each job period, summed over all job periods of a subject. The cumulative index was thereafter categorized according to the quartiles of the exposure distribution among controls.

Statistical Analyses

Logistic regression models were fitted to calculate odds ratios (OR) and 95% confidence intervals (CI) of lung cancer associated with indices of DME exposure. To further explore residual confounding we repeated the analyses on cumulative DME exposure in never-smokers and among subjects who had never been employed in a "List A" job. A "List A" job represents a list of occupations and industries known to present an excess risk of lung cancer, which was identified by Ahrens and Merletti in 1998 (21) and updated by Mirabelli and coworkers in 2001 (22). We also investigated the DME effect in women separately. Additional sensitivity analyses consisted of (*1*) excluding the AUT-Munich study because of a low response rate (41%) among controls; (*2*) comparing the results of studies with controls recruited from the population versus the studies using hospital controls because the latter possibly are more prone to selection bias in case of different study bases for cases and controls; and (*3*) excluding "ever-farmers" because farmers may be particularly inclined to this kind of selection bias (23). The subjects unexposed to DME were the reference category in each of the analyses.

P values for linear trend were obtained by applying a logistic regression model including respective continuous variable. The trend was calculated among all subjects.

We made three levels of adjustment: (*1*) adjusting for age group (<45, 45–49, 50–54, 55–59, 60–64, 65–69, 70–74, and 75+), sex, and study; (*2*) additionally adjusted for ever-employment in a "List A" job (yes/no); and (3) additionally adjusted for tobacco smoking (log[cigarette pack-years+1]) and time-since-quitting smoking cigarettes (current smokers; stopping smoking 2–7, 8–15, 16–25, 26+ yrs before interview/diagnosis; and never-smokers). Current smokers were persons who had smoked greater than or equal to one cigarette per day for greater than or equal to 1 year, and included those who had stopped smoking in the last 2 years before diagnosis or interview. The cigarette pack-year was calculated as follows: $\sum$duration $\times$ average intensity per day/20.

Meta regression models were used to explore study-specific ORs and extent and sources of heterogeneity, and forest plots were used to visualize the results. We compared the DME effect in small versus large studies (> /< 1,500 subjects); old versus recent studies (end of data collection before or after 1995); hospital-based versus population-based case–control studies; and by study and region according to Globocan for Western Europe, Northern Europe, Central Europe, Eastern Europe, Southern Europe, and Northern America (24). The heterogeneity was assessed using a chi-squared test with inverse variance weights. The extent of heterogeneity between OR estimates was assessed as a percentage (I^2) (25).

All analyses were conducted using Stata v.11.0 for Windows (StataCorp LP, College Station, TX). We used the Stata command "metan" for the meta regression analyses.

RESULTS

The study sample comprised 13,479 cases and 16,510 controls. Subjects providing incomplete information for calculating duration of jobs or cumulative smoking were omitted (175 cases and 228 controls), leaving 13,304 cases and 16,282 controls for these analyses.

The data were collected in 41 centers in 13 countries between 1985 and 2005. The response rates ranged between 68% (HdA) and 98% (LUCA) among cases, and 41% (AUT-Munich) and 100% (INCO-Hungary) among controls. The hospital-based case–control studies generally achieved a higher response rate. The overall response rate weighted by the size of the study population was 82% among cases and 67% among controls. The MORGEN study is derived from a prospective cohort study conducted in The Netherlands. After invitation by letter 45% agreed to participate in the cohort study and completed a baseline questionnaire; the mean follow-up time until diagnosis was 5.3 years (SD 2.7).

Table 2 describes characteristics of the study population. The median age was 64 years in men and 62 years in women. Six percent of cases were never-smokers, versus almost 30% among the controls. The PARIS study was restricted to smokers. The proportion of current smokers was 65.2% among cases and 31.6% among controls. The mean of cumulative tobacco consumption (cigarette pack-years) was 38.9 (SD 27.8) in cases and 19.2 (SD 23.2) in controls. The mean time since quitting smoking was 4.6 (SD 8.7) years among cases and 11.6 (SD 13.5) years among controls. Twelve percent of the cases (14.1% men and 2.7% women) and 7.8% of controls (9.4% men and 1.4% women) have held a job known to entail an excess risk of lung cancer ("List A" job). Based on the DOM-JEM assignment, the lifetime prevalence of occupational DME exposure among control subjects was 13.6% in women and 42.4% in men.

Definition of abbreviations: CI = confidence interval; OR = odds ratio.

* The categories represent the quartile distribution of cumulative diesel motor exhaust exposure among exposed controls.

† OR1 is adjusted for age, sex, study, and ever-employment in a "List A" job (*see* text for details).

‡ OR2 is additionally adjusted for pack-years and time-since-quitting smoking.

§ Test for trend, *P* value obtained using the continuous variable for cumulative exposure.

Among women, the highest proportion of DME-exposed controls was found in Germany (24.2%) and the lowest in France (0%), whereas in men the highest proportion was found in the United Kingdom (66.1%) and the lowest in Romania (23.9%). Among control subjects, very few women (<1%) had experienced high levels of occupational DME exposure, versus 8.3% among men. The proportion of highly exposed men among control subjects was particularly high in the United Kingdom (20.6%); Germany (11.5%); Hungary (10.6%); and Canada (9.7%).

Risk estimates as shown in Tables 3–5 were based on models adjusting for age, sex, study, and ever-employed in a job known to entail an increased lung cancer risk (OR1); and OR2 additionally adjusted for cigarette pack-years, and time-since-quitting smoking cigarettes. In the subsequent text we refer to the results adjusted for smoking (i.e., OR2) or else we indicate what adjustments were made.

Table 3 shows the OR for lung cancer associated with cumulative DME exposure. We observed a significant dose–response trend (P value < 0.01). In the analysis by exposure category the CI of the OR for the highest exposure category excluded unity (OR, 1.31; 95% CI, 1.19–1.43). A random effects meta regression rendered essentially similar results (OR, 1.26; 95% CI, 1.14–1.40) (Figure 1). The OR for the highest quartile of DME exposure, when only adjusted for age, sex, and study, was 1.42 (95% CI, 1.31–1.54).

Figure 1 illustrates the study-specific OR for the highest quartile of cumulative DME exposure versus the never DME exposed. INCO-Romania, INCO-UK, LUCA, EAGLE, and MORGEN showed OR less than 1, whereas the OR in the other studies ranged between 1.16 (INCO-Czech Republic) and 1.77 (INCO-Poland). The OR decreased 10–20% in most countries, and the heterogeneity between the studies expressed as I^2 decreased from 32.5% to 13.8%, when adjusting for smoking (pack-years and time-since-quitting smoking).

In subgroups analyses, the OR for lung cancer among never-smokers was 1.26 (95% CI, 0.90–1.78) in the highest exposure category of cumulative DME exposure; no trend was observed

Definition of abbreviations: CI = confidence interval; OR = odds ratio.

* OR1 is adjusted for age, sex, study, and ever-employment in a "List A" job (*see* text for details).

† OR2 is additionally adjusted for smoking pack-years, time-since-quitting smoking.

‡ Test for trend, *P* value obtained by using respective continuous variable.

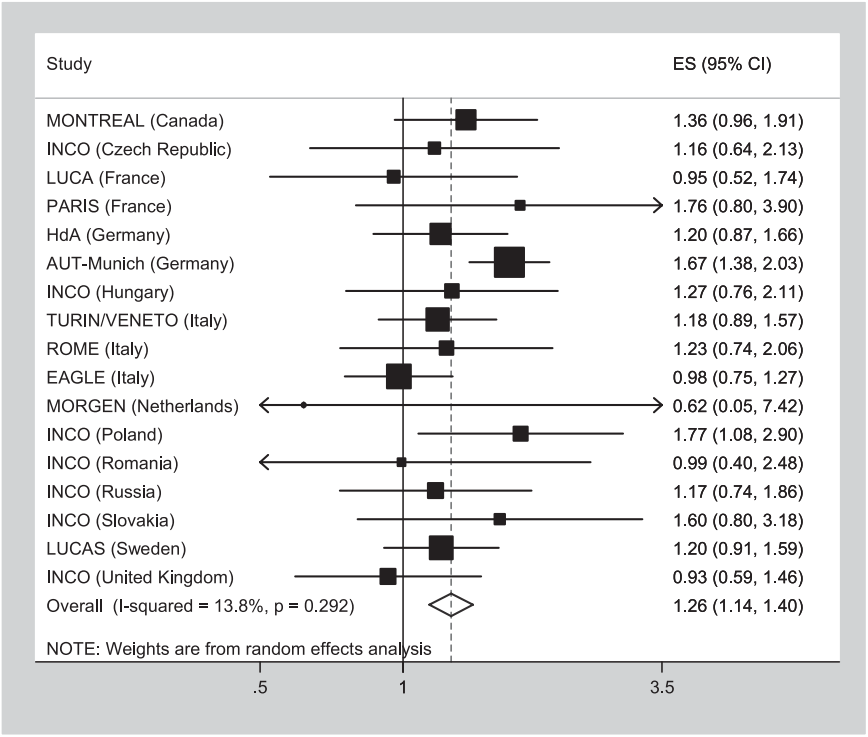

Figure 1. Study-specific odds ratios for the highest quartile of cumulative diesel motor exhaust exposure compared with never-exposed, adjusted for age, sex, cigarette pack-years, time-since-quitting smoking, and ever-employment in a "List A" job. CI = confidence interval; ES = odds ratio.

($P = 0.28$). The results in workers never employed in "List A" jobs were comparable with the overall results (i.e., an increased OR for lung cancer in the highest exposure category; OR, 1.35; 95% CI, 1.23–1.49, with a significant exposure–response trend [P value < 0.01]). Among women, the OR for lung cancer in the highest DME exposure category was 1.58 (95% CI, 0.96–2.59). In men, an OR 1.28 (95% CI, 1.17–1.41) for the fourth quartile was observed, with a significant exposure–response trend ($P < 0.01$).

The risk estimates were very similar for population-based and hospital-based case–control studies: for the highest quartile of cumulative DME exposure OR 1.30 (95% CI, 1.17–1.44) versus 1.31 (95% CI, 1.09–1.59). Excluding the AUT-Munich study lowered the OR for lung cancer to 1.22 (95% CI, 1.10–1.35), whereas excluding ever-farmers resulted in an OR 1.28 (95% CI, 1.15–1.42). The significant exposure–response trends remained (excluding AUT-Munich P value < 0.01; excluding farmers P value < 0.01).

The effect of cumulative DME exposure was similar for different types of lung cancer (*see* Table E1 in the online supplement). The OR for non–small cell lung carcinoma among men was 1.27 (95% CI, 1.14–1.40) in the highest exposure category of cumulative DME exposure, whereas it was 1.44 (95% CI, 0.83–2.50) among women. For small cell lung carcinoma, the OR in the highest exposure category was 1.31 (95% CI, 1.10–1.55) in men and 3.82 (95% CI, 1.51–9.67) in women.

In Tables 4 and 5, we estimated lung cancer risk in relation to duration of exposure. The OR for lung cancer associated with only low levels of DME exposure (Table 4) was close to 1, until 30 years of duration. The OR associated with greater than 30 years of exposure to low levels of DME exposure versus never-exposed was 1.17 (95% CI, 1.07–1.29). Workers exposed to high levels of DME exposure (Table 5) experienced an increased risk of lung cancer within a short period of high exposure (<10 yr; OR 1.28; 95% CI, 1.14–1.45). The highest risk was observed after 21–30 years of high level exposure (OR 1.52; 95% CI, 1.15–2.02).

We observed no significant heterogeneity for the effect of DME in the highest quartile of cumulative exposure versus the never-exposed across studies (I^2 13.8%; P value = 0.29). However, when exploring other potential sources of heterogeneity we found a difference in the effect of DME in the studies completed before 1995 (OR 1.49; 95% CI, 1.32–1.68) compared with the more recent studies (OR 1.19; 95% CI, 1.04–1.36); with a pooled OR 1.34 (95% CI, 1.07–1.67), $I^2 = 83.9\%$, and P value 0.01. Geographic region was also associated with significant heterogeneity, with the highest risk estimate in Western Europe (OR 1.51; 95% CI, 1.30–1.76) and the lowest in Southern Europe (OR 1.07; 95% CI, 0.90–1.28). The pooled OR for the highest quartile of cumulative DME exposure across regions was 1.29 (95% CI, 1.11–1.50), $I^2 = 59.8\%$, and P value 0.04. The effect of DME in large and small studies was not significantly different (P value = 0.13) with the pooled OR 1.33 (95% CI, 1.14–1.54). Likewise, the effect of DME was not influenced by the type of controls (P value = 0.82) with the pooled OR 1.36 (95% CI, 1.24–1.48).

DISCUSSION

We used the recently established database from the SYNERGY project to explore the possible association between occupational DME exposure and lung cancer. The SYNERGY database is unique in the sense that it comprises lifetime occupational data and detailed smoking information for more than 13,000 cases and 16,000 controls from 11 case–control studies in Europe and Canada. We found an exposure–response relationship between occupational DME exposure, measured by a semiquantitative score of cumulative exposure, and lung cancer. In the analysis by categories of the cumulative dose score, the conventional limit for statistical significance of the OR was reached in the fourth quartile of cumulative dose. The results were similar in women, in never-smokers, and in workers never employed in jobs known to entail increased lung cancer risk, although the ORs in the highest quartile did not attain statistical significance in all subgroup analyses. Whereas subgroup analyses are helpful in limiting residual confounding, they lead to considerable loss of power. This is especially true for women and never-smokers

TABLE 5. LUNG CANCER RISK BY YEARS OF EXPOSURE TO HIGH LEVELS OF DIESEL MOTOR EXHAUST

Duration of Diesel Motor Exhaust Exposure (*yrs*)	Case/Control	OR1*	95% CI	OR2†	95% CI
0	7,676/10,320	1.00	Reference	1.00	Reference
1–10	858/696	1.48	1.33–1.65	1.28	1.14–1.45
11–20	228/208	1.34	1.10–1.62	1.21	0.98–1.51
21–30	149/108	1.75	1.36–2.26	1.52	1.15–2.02
>30	126/101	1.59	1.22–2.08	1.45	1.07–1.96

and makes the OR estimates unstable and the interpretation of the confidence intervals in the individual categories of exposure difficult. When we distinguished workers with low-intensity exposure from those with high exposure, the latter showed excess risks with as low as 10 years duration, although those with low-intensity exposure showed elevated risks only after 30 years and more of exposure. Our results are to a large extent in line with previous research (8, 16), although most previous studies could not control for major potential confounders, such as cigarette smoking and occupational exposures, and have not had as large sample sizes as ours to assess risks in different subgroups.

Three papers on lung cancer risk after diesel exposure have been published from the studies included in this pooled analysis (9, 26, 27). Exposure to DME in these studies was assessed on a case-by-case basis by local experts. An increased risk of lung cancer and a dose–response trend was observed in Germany (AUT-Munich and HdA combined; OR 1.43; 95% CI, 1.23–1.67) and Sweden (LUCAS; OR 1.40; 95% CI, 0.90–2.19), but not in Italy (Turin/Veneto; OR 1.04; 95% CI, 0.79–1.37) (9, 26, 27). Our country-specific results for ever high exposure obtained by using the DOM-JEM were similar to those reported in these previous studies: Germany (OR 1.54; 95% CI, 1.31–1.81); Sweden (OR 1.10; 95% CI, 0.65–1.85); and Italy (OR 1.00; 95% CI, 0.80–1.24).

The prevalence of DME exposure was higher in the current analysis compared with the original studies that had estimated diesel exposure using expert case-by-case assessment, or specific project JEMs. This is a consequence of the ratings in the DOM-JEM (e.g., farmers are assigned low DME exposure and represent a relatively large proportion of the exposed population in some of the studies). In the INCO-Hungary study the prevalence of DME exposure decreased by 19% when farmers were excluded, whereas the decrease was only 1% in INCO-UK. The high prevalence of exposure is also a consequence of the nature of a JEM, namely to assign everybody in a given job code the same exposure, whereas individual assessments give the opportunity for attributing exposure to some people in a job but not others, and to take into account an increasing trend of diesel engines over time. This may contribute to multiple dimensions of exposure misclassification, but is not related to disease status and thus would most often lead to an attenuation of the OR estimates.

We excluded farmers in sensitivity analyses assuming that farmers living in rural areas may belong to specialized cancer hospitals with a larger catchments area than the region from which hospital controls were enrolled, and which could cause selection bias as has been shown in a previous small case–control study (23). The OR for low DME exposure greater than 30 years decreased from OR 1.17 (95% CI, 1.07–1.29) to 1.07 (95% CI, 0.95–1.20) when excluding farmers. The OR for the fourth quartile of cumulative DME exposure changed from OR 1.31 (95% CI, 1.19–1.43) to OR 1.28 (95% CI, 1.15–1.42). The corresponding risk estimates when comparing studies with population controls versus hospital controls were virtually the same, *P* value for heterogeneity 0.82. Thus, these data do not show an important selection bias as a result of potentially different study bases for cases and controls.

A large group of workers with DME exposure are drivers; more than 20% of the study population has worked as driver during their working life. Drivers are exposed to high exposure levels of hazardous substances when they smoke in their vehicles, and are exposed to second-hand smoke from coworkers or other passengers (28). This residual confounding by tobacco smoke among drivers could contribute, even if minimally, to the increased risk seen among low-exposed workers.

In most scenarios nondifferential exposure misclassification leads to attenuation of OR estimates; however, our large study size and the high prevalence of DME exposure may have given SYNERGY enough power to detect a statistically significant OR, even in the presence of underestimation (29, 30). The DOM-JEM is based on job titles only and is therefore a highly standardized tool (31, 32), which diminishes the likelihood of both potential recall and reporting bias. Selection bias has been discussed previously in relation to farmers, but can also occur if participation differed by other subgroups of cases and controls with different probability of DME exposure. We assessed this by excluding the AUT-Munich study (the largest individual study with low response rate among controls); the ORs decreased slightly but did not change the overall results. Thus, a strong selection bias as a result of differences in nonparticipation among cases and controls is unlikely.

Heterogeneity of relative risk estimates may result from variation in many factors, including the background risks of lung cancer. The most influential risk factor for lung cancer is the smoking pattern in respective country (33). Indeed, lung cancer mortality varies largely in the countries included in the analyses and has changed dramatically over the last 50 years; lung cancer mortality peaked around 1970 in the United Kingdom, whereas it peaked as late as around 2000 in Poland and Hungary (34). Exposure to other lung carcinogens may also have differed as a result of the level of industrialization in each local setting. The frequency of employment in jobs known to entail increased lung cancer risk among the controls in the current study, ranging from 3% in MORGEN (The Netherlands) to 16% in HdA (Germany), was approximately controlled for in the analyses.

Among the strengths of this analysis are the large sample size, the good quality of data on occupational history and smoking, and the fact that the exposure assignment for DME was based on a JEM created by experts. Among the limitations are that some of the centers used hospital-based control selection, the JEM did not take into account the changes in

the use of diesel engines over time, and it was not possible to estimate absolute concentration levels for DME.

Our results reflect the effects of the DME exposure present before and up to the time when the studies were conducted. Modern engine emissions have become cleaner in the last 20 years (e.g., by the use of low-sulfur fuel and particle traps on vehicles) (35). However, the number of emitted particles may still be high and the consequences on the potential carcinogenicity are not clear. In addition, old types of engines and other sources of DME (e.g., ships, generators, diesel powered tools, paving equipment, and so forth) continue to lead to DME exposure; our results suggest that DME exposure may contribute to the current lung cancer burden.

Conclusions

Our results show a small consistent association between occupational exposure to DME and lung cancer risk, and significant exposure–response trends. When the exposure score was categorized in quartiles, the OR associated with the highest quartile was statistically significant. This association is unlikely to be entirely explained by bias or confounding, which we addressed by adjusted models and analyses in subgroups not exposed to potential confounders. Cohort studies among heavily exposed occupations with quantitative exposure measurements may shed further light on the risk assessment.

APPENDIX B: HEALTH IMPACTS OF EXPOSURE TO NEAR- ROADWAY POLLUTION

1. Infographic by USC
2. References
3. Selected key scientific articles

Recent research on risks from...

LIVING NEAR BUSY ROADS OR TRAFFIC POLLUTION

Who is at risk, and what might the risks be?

BABIES
- weigh less at birth
- born early (premature)
- have problems with behavior, learning or autism

PREGNANT WOMEN
- pregnancy problems
- high blood pressure

CHILDREN
- asthma
- hospital for asthma
- ear, nose, throat infections
- smaller lungs
- obesity

TEENAGERS
- smaller lungs for life if exposed since early childhood

ADULTS
- heart disease
- stroke

SENIORS
- heart attacks
- lung problems
- memory problems
- shorter life

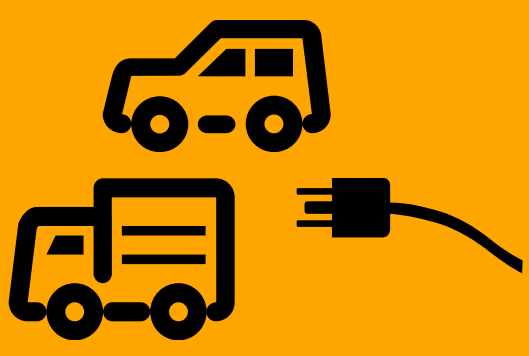
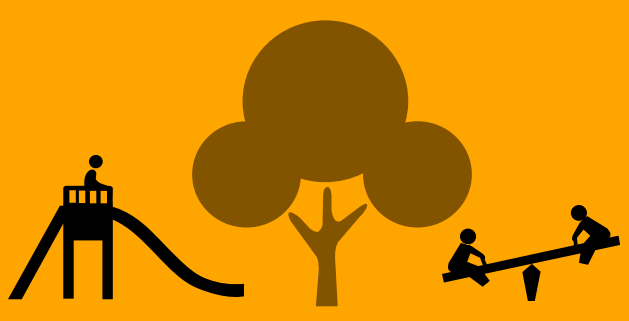
WHAT YOU CAN DO:

Join a group that is working to reduce air pollution.

Consider biking instead of driving for trips close to home.



Carpool to school or work or use public transit.



Support building more public transit (such as buses and rail lines) so that fewer people have to use cars.

Support producing cars and trucks that are electric or use cleaner fuels to reduce tailpipe emissions.

Learn more about pollution in your own community.

Pregnant Women

Pregnant women are particularly vulnerable to air pollution, including pollution near busy roads and freeways. Studies show that women may develop high blood pressure or diabetes during pregnancy if they are close to high levels of air pollution. This type of diabetes is called "gestational" and often goes away after the baby is born. Some pregnant women develop an illness called "pre-eclampsia" that can result in high blood pressure and possible kidney damage. Below are selected health studies on these topics.

Developing Fetus and Babies

Many harmful health problems can happen to a developing fetus when a pregnant mother lives near high levels of air pollution, including pollution from traffic. There have been studies for a number of years on low-birth weight and babies being born early, and recently studies have found changes to the developing brain. This might lead to behavior or learning or other "cognitive" problems, including autism, ADHD, and schizophrenia. Below are selected health studies on these topics.

Low birth weight (weigh less when born) or growth retardation (fetus is slower growing)

Children

For children who live or go to school near high levels of air pollution when they are young (or even before they were born), this can lead to health problems. These include lungs not working and growing as fast as they should, if exposed to pollution when they were young. Children can also develop asthma from air pollution near busy roads, are also likely to go to the hospital for asthma attacks. Studies show more ear, nose, and throat infections for children who are near this kind of air pollution from traffic. New studies may link a higher chance of obesity in children who live near busy traffic or if their mothers were regularly near traffic pollution when pregnant. Below are selected health studies on these topics.

Asthma

Teenagers

Many of the health problems from air pollution (described above) for children can go into the teenage years. For teenagers, by the time they have graduated from high school or soon after, most teens' lungs will have reached "maturity," meaning they will not likely grow any further. So if a teen's lungs are smaller or don't work as well at age 18, the lungs may not grow and get healthier as they grow into and adult. Below are selected health studies on these topics.

Smaller lungs for life if exposed since early childhood

Adults

Several recent studies show that being near air pollution for a long time over your life can give people a higher chance of having heart problems. This is for ambient pollution (regional pollution that everyone in a community breathes) and traffic pollution (near-roadway pollution). This pollution can lead to more cardiovascular (heart) disease, and being near air pollution for a long time over your life can lead to more deaths from heart disease. There are now more studies showing links between traffic pollution and stroke. One study showed that sudden cardiac deaths (including from stroke) is linked to traffic exposure in middle-aged women. Below are selected health studies on these topics.

Seniors (middle aged adults and older)

One study of women with an average age greater than 60 were more likely to die from sudden cardiac deaths (including heart disease and stroke) if they lived near traffic pollution. Some studies have linked road traffic noise to stroke, but another study found that traffic air pollution was linked to stroke even when noise was taken into account. Several studies show that traffic pollution is linked to premature death (dying younger than one might have otherwise). Below are selected health studies on these topics.

Preeclampsia · Perinatal outcome · Placenta · Pregnancy complications · Air pollution · Traffic · Road density · Late-onset preeclampsia

Abstract

Introduction: Previous epidemiological studies indicate an association between maternal exposure to air pollution and an increased risk of hypertensive disorders in pregnancy. We analyzed the association between the occurrence of mild/severe and early-/late-onset preeclampsia (PE) and traffic-related air pollution (TRAP). ***Materials and Methods:*** Based on retrospective data, 50 pregnant women with PE were selected and matched with a control group of healthy pregnant women according to their age, parity, and number of fetuses. The total length of major roads around the women's home within a radius of 100, 200, 300, and 500 m and the distances from the domicile to the nearest 'first class' main road and freeway were used as a proxy indicator of TRAP. We compared a PE subgroup and control group in terms of their exposure to TRAP. ***Results:*** Late-onset PE cases showed a significantly higher occurrence with density of major roads within a radius of 100–300 m compared to early onset cases ($p = 0.006$; 0.02; 0.04). In addition, a significantly shorter distance to the nearest 'first class' main road was observed in late-onset PE cases ($p = 0.0078$). ***Conclusions:*** Exposure to TRAP during pregnancy was associated with an increased risk for the development of late-onset PE.

Introduction

Preeclampsia (PE) is a serious complication of the second half of pregnancy in up to 8% of all pregnancies. It is one of the 3 leading causes of maternal morbidity and mortality worldwide [1]. PE is clinically defined as the new onset of hypertension (blood pressure ≥140/90 mm Hg at least on 2 measurements 6 h apart from each other) and significant proteinuria (>0.3 g/24 h) after 20 weeks of gestation. The severe type of PE is specified as hypertension over 160/110 mm Hg and proteinuria above 0.5 g/24 h [2]. Furthermore, signs of a significant organ involvement like neurological symptoms, renal failure or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet) belong to the category of severe PE [3]. Depending on the time of appearance of the first clinical symptoms, PE can also be classified into 2 distinct subtypes. Early onset is defined as less than 34 weeks of gestation, while late-onset is

defined as after 34 + 0 weeks of gestation [1, 4–7]. Early-onset PE is a rare disease with a high maternal and neonatal morbidity and mortality [5]. Late-onset PE, however, has a lower maternal and fetal morbidity and occurs more frequently. Besides the different clinical aspects and maternal and fetal outcomes, there is a discussion about different etiologies of these 2 subtypes. Several studies propose that generalized endothelial dysfunctions in the placenta and the impaired trophoblastic invasion of the maternal placental bed in early pregnancy might be the origins of the early-onset disease [3]. These 2 factors may lead to systemic endothelial cell dysfunction and systemic inflammation with neutrophil activation in the maternal body [8, 9]. PE presenting at term is associated with a lower frequency and severity of fetal growth restriction compared to early-onset PE. Late-onset PE could be hypothesized to present a process leading to maternal endothelial damage, which is unrelated to impaired early trophoblast invasion [10]. Predisposing cardiovascular factors or metabolic risks for endothelial dysfunction as part of an exaggerated systemic inflammatory response might dominate the origin of late-onset PE [11–13]. Currently, the only causal treatment for PE is delivery and the removal of the placenta. The prediction of PE is a major challenge in contemporary obstetrics, and some authors could recently show added value of angiogenic factors for the prediction of early- and late-onset PE in the first trimester of pregnancy [14].

Major risk factors for the development of PE [12, 15] are previous chronic hypertension, kidney disease, diabetes mellitus, nulliparity, obesity, multiple pregnancies, maternal age >40 years, African-American race [16], and family history of PE. It is known that local air pollution exposure, especially pollution due to motor vehicle traffic [17], is associated with adverse cardiovascular and respiratory effects like systemic inflammation, elevated blood pressure and asthma [18, 19]. Previous studies also indicate a potential harmful effect of local air pollution on pregnancy outcome, including an increased risk of preterm delivery and PE [20–22]. Recently, a meta-analysis including 17 studies evaluated the exposure to ambient air pollution and pregnancy-induced hypertensive disorders. Most studies measured air pollutant levels like nitrogen oxides (NO_2, NO_x), particulate matter (PM_{10}, $PM_{2.5}$), carbon monoxide (CO), ozone (O_3), but few took traffic density and the proximity to major roads into account, which can be used as estimates of air pollution. The meta-analysis showed an increased risk of hypertensive disorders in pregnancy including all pollutants as well as the proximity to major roads and traffic density [23]. In this context, several studies have reported that traffic-related air pollution (TRAP) is associated with endothelial dysfunction, a potential predictor of PE [24, 25]. Air pollutants may also contribute to an anti-angiogenic state which can also lead to PE [26]. The aim of the present study was to analyze the association between the occurrence of PE and TRAP in the North Western area of Switzerland in a case-control study. The PE cases were stratified into mild/severe and early-/late-onset subgroups according to the common definitions [6] and analyzed for their association with air pollution.

Materials and Methods

Study Design and Study Population

This case-control study was performed at the University Hospital of Basel, Switzerland. The catchment area of the study was the Canton of Basel-City and its surroundings (Canton of Basel-Country). A few study participants were enrolled from the Cantons of Aargau, Solothurn, Zurich and Berne. Based on retrospective data from the electronic medical records of the Department of Obstetrics and Fetomaternal Medicine and the home addresses, indicated at booking, 50 pregnant women were selected for the study group. These women were treated for PE and sent to our institution between January 1, 2011, and December 31, 2011. The criteria included were all singleton or multiple pregnancies after 20 + 0 weeks of gestation. The excluded criteria were pregnancies before the 20 + 0 weeks of gestation, the women's domicile outside of Switzerland, women with an abortion due to PE or eclampsia before the 24th week of gestation as well as fetuses with severe malformation. The study group was matched with a healthy control group of 50 pregnant women with uncomplicated pregnancies. Age at delivery (± 1year, if necessary), parity and number of fetuses (singleton or twin pregnancy) were used as matching criteria. According to our statistics, there were 79 women in total treated for PE at the University Hospital of Basel in 2011. Overall, 2,286 births' were registered at our institution. This study was approved by the Ethics Committee of Basel (Ethikkommission beider Basel).

TRAP Exposure

In the present study, the exposure to TRAP, especially nitrogen dioxide (NO_2), particulate matter ($PM_{2.5}$, PM_{10}), sulfur dioxide (SO_2) and carbon monoxide (CO) [27], was estimated by a surrogate measure of road density in the surroundings, in particular the densities of major roads, which is defined as a combination of all freeways and 'first class' main roads (at least 6 m wide) [28, 29]. The geographic information system (GIS) data with the road network of Switzerland was provided by the Swiss Federal Office of Topography (swisstopo) [30]. Two parameters for estimating the road density were defined; first, the total length of all major roads within a radius of 100, 200, 300, and 500 m around the geocoded location of each woman's home during their pregnancy, and second, the distance in meters from each woman's domicile to the nearest 'first class' main road and freeway.

Statistical Analysis

The statistical data set included a total of 100 pregnant women, whereof 50 women developed PE during pregnancy (study group) and 50 women showed no health problems (control group). PE cas-

Norris Medical Library
68.181.124.92 - 10/25/2017 7:50:42 PM

es differed in severity, 'mild' or 'severe', and in time of onset, 'early' or 'late'. Mean, standard deviation, median, minimum and maximum for each road density parameter were calculated for each group. Both case and control groups as well as each PE subgroup (mild vs. severe; early vs. late onset) were compared by a Mann-Whitney test. Statistically significant results were defined as $p \leq 0.05$.

Maternal and fetal characteristics were measured and differences between the case and control groups were tested using Fisher's exact test for continuous variables and the Kruskal-Wallis rank-sum test for categorical variables. p values were not adjusted for multiple testing. We did not perform a power calculation. Our main objective was the comparison between the case and control group.

Results

Subject Characteristics

We included 100 pregnant women and 106 newborns in the study. Maternal and fetal characteristics are represented in tables 1 and 2. The control group was matched for maternal age and parity, but, due to the retrospective design and logistical restrictions, not for other risk factors like hypertension, previous PE or twin pregnancy, which could increase the risk for PE. All relevant diseases were absent in the control group, with the exception of 1 case of asthma (table 1: 'other disease'). There were 2 women with gestational diabetes and 2 with preconceptional diabetes. Newborns from mothers suffering from PE had a preterm birth more often, were born by cesarean section and transferred to the neonatal intensive care unit.

Cases versus Control

Figures 1 and 2 show the descriptive analyses of road density parameters for the study versus the control group. The control group showed a significantly higher total length of major roads within a radius of 500 m compared to the study group (fig. 1). For all other road density parameters, no statistically significant difference between study and control group was found.

Early- versus Late-Onset PE Cases

Descriptive analyses of road density parameters for early- versus late-onset PE cases are shown in figures 3 and 4.

Late-onset PE cases showed a significantly higher occurrence with a total length of major roads within a radius of 100, 200, and 300 m (fig. 3) and a significantly shorter distance to the nearest 'first class' main road compared to early-onset PE cases (fig. 4). In addition, in late-onset PE cases, both a higher total length of major roads within a radius of 500 m and a shorter distance to the nearest freeway were found, although these differences were not statistically significant.

Mild versus Severe PE Cases

No significant difference was found in any road density parameter between severe and mild PE cases. However, some tendency in the results could be observed: severe PE cases showed a higher total length of major roads within all radiuses (fig. 5) and a shorter distance to the nearest freeway and to the nearest 'first class' main road compared to mild PE cases (fig. 6).

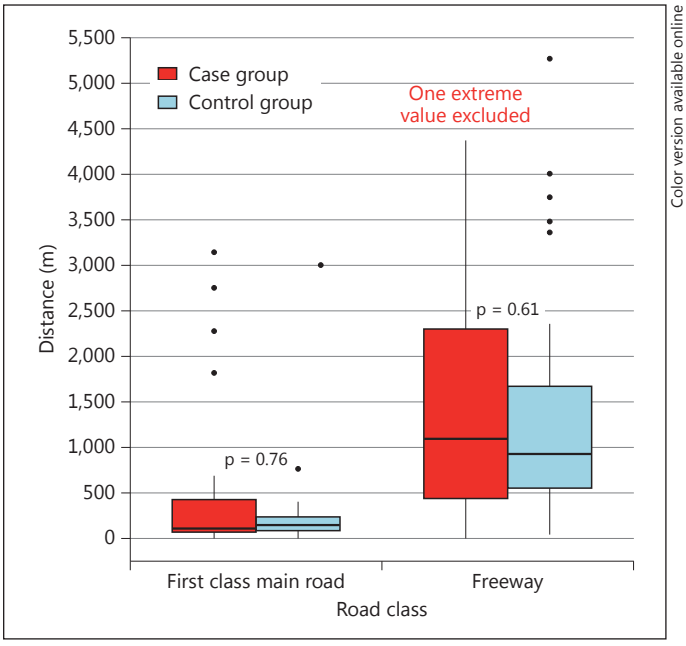

Fig. 2. Distance of the women's domiciles to the nearest freeway and the nearest 'first class' main road for cases (n = 49; one extreme value was excluded for better presentation of the figure) and controls (n = 50).

Discussion

There is growing interest in analyzing environmental factors and influences on pregnancy and neonatal outcome [22, 31–33]. According to our findings, women who developed late-onset PE were exposed to significantly higher TRAP in general than women who had early-onset PE. Various studies suggest that a late onset of PE impaired trophoblastic invasion of myometrial arteries and is phenotypically balanced unless predisposing factors will set off a cascade of placental and systemic inflammation [12]. In general, it is thought that early-onset PE involves a placental defect, which is not as evident in late-onset PE. It appears that late-onset PE involved a different inflammatory component [34]. The impaired trophoblastic invasion of the placental bed and the following cascade in the early onset of PE might already determine the severity of the disease, and external factors like TRAP become less obvious. Local air pollution may be an important risk factor for the development of late-onset PE. Epidemiological studies highlighted an association between a steeper increase in arterial blood pressure in pregnancy, an increased risk for pregnancy-induced hypertension, PE and a higher PM_{10} exposure [22]. Potential pathways for a pro-hypertensive effect of air pollution have been suggested to include an increase in sympathetic tone and/or the modulation of basal systemic vascular tone as a result of increased endothelin-1 concentrations as well as

impairment of nitric oxide–induced vasodilation. Furthermore, exposure to air pollution might result in systemic inflammation, which could predispose to the development of gestational hypertensive disorders [22, 35]. Few studies have investigated PE and gestational hypertension. A California birth cohort study of air pollution investigated PE based on birth certificates and reported positive associations with higher carbon monoxide (CO) and sulfur dioxide (SO_2) exposures during pregnancy [27]. Two further studies conducted in the USA reported an increased risk with ambient CO, $PM_{2.5}$ or NO_x exposures [22, 31]. More recently, Lee et al. [7] reported that exposure to particles, mostly $PM_{2.5}$ and ozone in the first trimester, may increase the risk of developing PE and gestational hypertension. In contrast to these studies, we found no significant association of road density at the women's domicile with an incidence of PE. This may be due to the characteristics of the control group: healthy pregnant women going to the University Hospital have a nearby domicile, i.e. in an urban setting. The larger radiuses (300 and 500 m) may reflect an urban versus rural environment rather than a TRAP coming from a closer source (radiuses 100 – 200 m). Nevertheless, considering previous studies [7, 22, 27, 31], data suggest a detrimental effect of near road density on any onset of PE: the study group showed a higher total length of major roads within the shorter radiuses of 100 and 200 m. The lack of statistical significance might be determined by the relatively small number of study participants or the origin of the participants, which belonged mostly to Caucasians. To our knowledge, one research group from Sweden has also investigated possible associations between PE and air pollution by using road density as a proxy indicator of TRAP [20]. Traffic density within a radius of 200 m has been observed. According to their results, PE was associated with high traffic density, but the odds ratio was not significant. Our results were in agreement with the previous research if we only considered radiuses of 100 and 200 m.

No significant evidence was found for an association of local air pollution with the severity of PE in this study. Nevertheless, a potential association between the occurrence of severe PE cases and higher traffic air pollution could be shown.

The current study provides, for the first time, data and references for the local situation in Switzerland. Instead of birth certificates, we used detailed clinical data with accurate gestational age based on a first ultrasound and maternal parameters, which allowed us to classify the 2 subtypes of PE.

To date, there has only been 1 study reporting on the impact of air pollution on early- and late-onset PE separately [36]. They found the strongest associations observed for late-onset PE in relation to third-trimester exposure to fine particulate pollutants and for early-onset PE.

The present study could replicate a significant difference in exposure to TRAP between early- and late-onset PE. This observation may provide some further indices for the pathogenesis of PE. If the association between air pollution and pregnancy complications represents a causal relation, it would have profound implications for public health, particularly in countries with limited maternal health care.

The retrospective study design bears 2 caveats. First, we did not match for risk factors like hypertension, previous PE or twin pregnancy, which could increase the risk of PE. This could cause bias and has to be considered in the interpretation. Second, since changes of address during pregnancy were not considered in our study, the real duration at the residence of each woman during her pregnancy is actually uncertain. This could be a potential bias for calculating the local air pollution exposure.

The road density is just a proxy for TRAP. However, the roads are the source of TRAP and are the most relevant predictors in the currently most used air pollution models (Land Use Regressions and Dispersion models). The consequence of using a less precise exposure assessment (road density versus NO_2 modelling or measuring) could lead to less power and nonsignificant results. We could show that even by using a far more simple approach to estimate 'traffic-related air pollution' exposure, we found evidence of the effect.

Conclusions

Our study shows that the exposure to TRAP during pregnancy was associated with a significantly increased risk for the development of late-onset PE compared to the early-onset cases. No statistical significance, but a potential association between local air pollution exposure and severity of PE, as well as an association between the occurrence of PE in general and traffic exposure within radiuses of 100 and 200 m, were observed in this study. More prospective studies with more participants are needed to understand local air pollution as a possible risk factor for late-onset PE and its pathogenesis.

If the association between air pollution and late pregnancy complications represents a causal relation, it would have profound implications for public health, particularly in countries with limited maternal health care [20].

Association between Local Traffic-Generated Air Pollution and Preeclampsia and Preterm Delivery in the South Coast Air Basin of California

Jun Wu,[1,2] Cizao Ren,[2] Ralph J. Delfino,[2] Judith Chung,[3] Michelle Wilhelm,[4] and Beate Ritz[4]

[1]Program in Public Health, College of Health Sciences, and [2]Department of Epidemiology, and [3]Department of Obstetrics and Gynecology, School of Medicine, University of California, Irvine, California, USA; [4]Department of Epidemiology, School of Public Health, University of California, Los Angeles, California, USA

Background: Preeclampsia is a major complication of pregnancy that can lead to substantial maternal and perinatal morbidity, mortality, and preterm birth. Increasing evidence suggests that air pollution adversely affects pregnancy outcomes. Yet few studies have examined how local traffic-generated emissions affect preeclampsia in addition to preterm birth.

Objectives: We examined effects of residential exposure to local traffic-generated air pollution on preeclampsia and preterm delivery (PTD).

Methods: We identified 81,186 singleton birth records from four hospitals (1997–2006) in Los Angeles and Orange Counties, California (USA). We used a line-source dispersion model (CALINE4) to estimate individual exposure to local traffic-generated nitrogen oxides (NO_x) and particulate matter < 2.5 μm in aerodynamic diameter ($PM_{2.5}$) across the entire pregnancy. We used logistic regression to estimate effects of air pollution exposures on preeclampsia, PTD (gestational age < 37 weeks), moderate PTD (MPTD; gestational age < 35 weeks), and very PTD (VPTD; gestational age < 30 weeks).

Results: We observed elevated risks for preeclampsia and preterm birth from maternal exposure to local traffic-generated NO_x and $PM_{2.5}$. The risk of preeclampsia increased 33% [odds ratio (OR) = 1.33; 95% confidence interval (CI), 1.18–1.49] and 42% (OR = 1.42; 95% CI, 1.26–1.59) for the highest NO_x and $PM_{2.5}$ exposure quartiles, respectively. The risk of VPTD increased 128% (OR = 2.28; 95% CI, 2.15–2.42) and 81% (OR = 1.81; 95% CI, 1.71–1.92) for women in the highest NO_x and $PM_{2.5}$ exposure quartiles, respectively.

Conclusion: Exposure to local traffic-generated air pollution during pregnancy increases the risk of preeclampsia and preterm birth in Southern California women. These results provide further evidence that air pollution is associated with adverse reproductive outcomes.

Key words: air pollution, nitrogen oxides, particulate matter, preeclampsia, pregnancy outcome, preterm birth, vehicle emission. *Environ Health Perspect* 117:1773–1779 (2009). doi:10.1289/ehp.0800334 available via *http://dx.doi.org/* [Online 23 June 2009]

Preeclampsia is a multisystem disorder in pregnant women, which is characterized by elevated blood pressure, edema, and protein in the urine. Preeclampsia complicates an estimated 2–8% of pregnancies and is a major cause of maternal mortality and morbidities, perinatal deaths, preterm birth, and intrauterine growth restriction (Duley 1992; Sibai et al. 2005). Because the only cure is delivery of the baby and placenta, preeclampsia is the most frequent primary reason for elective nonspontaneous preterm birth, accounting for 30–35% of total preterm deliveries (PTD) (Goldenberg et al. 2008; Meis et al. 1998). Preeclampsia does not necessarily lead to spontaneous PTD, and the association between preeclampsia and spontaneous PTD depends on PTD subtypes defined by gestational age (e.g., very or moderately preterm) and pathway (e.g., membrane rupture or spontaneous onset of labor before membrane rupture) (Ananth et al. 1997).

More than half a million infants are born prematurely each year in theUnited States (Hamilton et al. 2006). Preterm birth is associated with 70% of neonatal deaths and up to 75% of neonatal morbidity (Challis et al. 2001). Extremely preterm infants who survive the neonatal period face an elevated risk of serious life-long health problems, including learning disabilities and other chronic conditions (Doyle 1995, 2008). A growing body of research has linked elevated air pollutant exposures to PTD at pollution levels typical of many U.S. cities (Maroziene and Grazuleviciene 2002; Perera et al. 2003; Ritz et al. 2000, 2007; Šrám et al. 2005; Wilhelm and Ritz 2005). So far, preeclampsia has been associated with air pollution in only two recent U.S. studies (Rudra and Williams 2006; Woodruff et al. 2008).

There is also a growing body of evidence linking pollutants found in traffic exhaust specifically to respiratory and cardiovascular diseases (Adar and Kaufman 2007; Delfino 2002; Heinrich and Wichmann 2004; Sarnat and Holguin 2007). Although data are limited to date (de Kok et al. 2006), evidence is emerging that fresh vehicle emissions contain more toxic compounds per unit of particle mass than do aged aerosols, in part because of the contribution of ultrafine particles (UFPs; < 0.1 μm in aerodynamic diameter), which are found in higher concentration closer to emission sources (Zhu et al. 2002). Fresh traffic emissions' toxicity may originate from a high concentration of organic components because particle number concentrations are orders of magnitude higher, increasing the surface area to which volatile and semivolatile pollutants such as polycyclic aromatic hydrocarbons (PAHs) and carbonyl compounds can adhere.

There is indirect evidence for adverse impacts of traffic-generated PAHs on birth outcomes from studies in the United States (Choi et al. 2006, 2008; Perera et al. 2003, 2004), Poland (Choi et al. 2006), and the Czech Republic (Dejmek et al. 2000). However, most previous birth outcome studies relied solely on data from air monitors operated by government agencies, which are usually sited to assess regional ambient pollution and are thus unlikely to adequately capture the high spatial heterogeneity of air pollutants directly emitted from traffic (Hitchins et al. 2000; Zhu et al. 2002). Two studies examined the impact of local traffic emissions specifically on PTD (Wilhelm and Ritz 2003; Yang et al. 2003), but both assigned exposures based on the distance to and/or level of traffic on major roadways near residences, a relatively crude measure of traffic exhaust that does not consider vehicle emission rates or meteorology (Jerrett et al. 2005). Two recent birth outcome studies (Brauer et al. 2008; Slama et al. 2007), however, employed more sophisticated techniques to model traffic-related air pollution based on land use regression (LUR) that yielded quantitative estimates for specific pollutants.

Because of population and economic growth and the lack of effective public transportation in the Los Angeles area, the amount of passenger traffic and of goods being moved

through this region is projected to increase substantially in the next decade (California Environmental Protection Agency 2006). Such rapid growth in traffic-related fossil fuel use is expected to occur worldwide (Energy Information Administration 2008), adding urgency to research evaluating the impact of increased vehicle emissions on reproductive health outcomes. To address this issue, in the present study we investigated the effects of local traffic-generated air pollution on preterm birth and preeclampsia based on the CALINE4 line-source dispersion model (Benson 1989), which is specifically designed for the assessment of traffic emissions from roads. We obtained health outcomes data from a perinatal database with detailed clinical data from a four-hospital network in southern Los Angeles County and Orange County, California, from 1997 to 2006.

Materials and Methods

Study population. Our racially and socioeconomically diverse study population resided in two areas of the South Coast Air Basin of California [see Supplemental Material, Figure 1 (doi:10.1289/ehp.0800334.S1 via http://dx.doi.org)] that exhibit a wide range of air pollution concentrations from mobile sources. One is located in southern Los Angeles County, north of the Ports of Los Angeles and Long Beach. The communities adjacent to the port are affected by major commuter freeways and main trucking routes for goods leading out of the port (Interstate 710); 15% of all containers arriving in the United States travel on this freeway (Beverly 2005). The other area is located in Orange County, southeast of the ports. Four major commuter and truck transport freeways traverse these neighborhoods. The study region also covers some suburban, low-traffic neighborhoods.

Birth data. We acquired all birth-related variables and antenatal information for pregnant women delivering during 1997–2006 within the Memorial Health Care System (MHCS), a four-hospital network (Chung et al. 2006). Poverty (percentage of population living below the poverty level) information by census block groups was obtained from U.S. Census 2000 data (U.S. Census Bureau 2004). No birth certificate data were used. The MHCS database included residential address at delivery, birth hospital, prenatal care insurance, maternal age and race/ethnicity, maternal medical history (heart disease, chronic hypertension, previous PTD), preeclampsia and other maternal complications during pregnancy (diabetes, pyelonephritis), parity (first birth vs. second or subsequent birth), gestational age, and the neonate's sex and birth weight. Gestational age was calculated according to delivery date and estimated date of conception (based on last menstrual period and ultrasound dating). We did not have diagnosis dates for preeclampsia; therefore, we could not determine when the disease first occurred.

A total of 105,092 neonatal records were extracted from the birth database. We successfully geocoded 92.8% of nonmissing residential addresses with exact matches to house number using the TeleAtlas Geocoding Service (http://www.geocode.com). A total of 81,186 singleton birth records remained in the data set for final analyses (77%) after excluding multiple gestations (n = 5,261; 5%), incomplete records including those without full residential address and those missing any covariate information (n = 12,666; 12%), and unsuccessfully geocoded residential addresses and addresses outside the study region (n = 5,979; 6%). Excluded births were similar to included births by study region (Los Angeles County and Orange County), demographics (age and race/ethnicity), and the prevalence of preeclampsia.

Air pollution exposure assessment. Background air pollutant concentrations may be high in the study region due to port activities and relatively heavy traffic regionwide. However, in this study we focused solely on local traffic-generated pollution to assess the potentially high toxicity of hypothesized causative agents (e.g., UFPs and PAHs) in traffic emissions. Our estimated pollutant exposures should be regarded as indicators of primary emissions from local vehicular traffic on top of background ambient levels [see Supplemental Material (doi:10.1289/ehp.0800334.S1)]. We modeled local traffic pollution using a modified CALINE4 dispersion model for two surrogate pollutants [nitrogen oxides (NO_x) and particulate matter ≤ 2.5 μm in aerodynamic diameter ($PM_{2.5}$)] originating from traffic emissions within 3 km of each residence (Benson 1989; Wu et al. 2005, 2009), assuming that at this distance we would capture most local traffic emissions but little regional pollution transported from upwind areas. CALINE4 is a Gaussian dispersion model that employs a mixing zone concept to characterize pollutant dispersion over the roadway. Major inputs to CALINE4 include meteorology (atmospheric stability, mixing height, wind, and temperature), roadway geometry and traffic activities, and vehicle emission factors. The performance of CALINE4 has been evaluated in a number of studies (Benson 1989, 1992; Broderick et al. 2005; Gramotnev et al. 2003; Levitin et al. 2005; Marmur and Mamane 2003). Previous studies have found moderate to high correlations (R = 0.55–0.95) of CALINE4-modeled estimates with measured variability of traffic-related air pollutants [e.g., NO_x and nitrogen dioxide] in urban communities (Gauderman et al. 2005; Jerrett 2006). Our recent study showed a high correlation (R = 0.87) of CALINE4-modeled monthly NO_x concentrations with measurements at nine monitoring sites in the Long Beach study area in December 2007 and April 2008 (Wu J, Lurmann F, Avol E, unpublished data).

A comprehensive traffic database with annual average daily traffic counts and gasoline and diesel vehicle fractions was constructed for the entire study region. Vehicle emission factors were obtained from the California Air Resources Board's EMFAC2007 vehicle emissions model (California Air Resources Board 2008). Paved road-dust emissions for $PM_{2.5}$ were based on in-roadway measurements (Fitz and Bufalino 2002). Hourly wind speed, direction, and temperature were obtained from the National Weather Service (National Climatic Data Center 2008). Summarized mixing heights by season and hour were obtained from the 1997 Southern California Ozone Study (Croes and Fujita 2003) and assigned to each modeled day based on season and hour.

Statistical analyses. PTD was defined as a birth at < 37 completed gestational weeks, moderate preterm deliveries (MPTD) as births at < 35 gestational weeks, and very preterm deliveries (VPTD) as births at < 30 gestational weeks. We defined preeclampsia as the occurrence of mild preeclampsia (blood pressure > 140/90 mmHg and proteinuria), severe preeclampsia (e.g., blood pressure > 160/110 mmHg and proteinuria with or without signs of end-organ involvement, including oliguria, liver function abnormalities, thrombocytopenia, headache), or hemolysis, elevated liver enzyme levels, and low platelet count (HELLP) syndrome at any time during pregnancy. Because hemolysis/HELLP is on the continuum of mild/severe preeclampsia and is relatively uncommon, we chose to combine this diagnosis with severe preeclampsia. Pregnancy trimesters were defined as gestational weeks 1–13, 14–26, and 27 weeks to birth.

We performed multiple logistic regression using the statistical package R (version 2.6.1; R Foundation for Statistical Computing, Vienna, Austria). Confounders were selected based on *a priori* knowledge and included maternal age, maternal race/ethnicity, parity, prenatal care insurance type [private, public (government-sponsored or self-pay), and unknown], poverty, season of conception, pyelonephritis (preterm analyses only), and diabetes (preeclampsia analyses only). We adjusted for maternal age as a continuous variable using a quadratic polynomial function. For the preeclampsia analyses, we excluded women who had preexisting chronic conditions such as hypertension and heart disease before pregnancy. We separately calculated odds ratios (ORs) and 95% confidence intervals (CIs) for increases in the interquartile range (IQR) for each pollutant exposure metric. ORs and 95% CIs were scaled to IQR increases in air pollutant variables to standardize and compare associations regardless

of pollutant concentration range or units of measurement (Lipfert and Wyzga 1999). In addition to using continuous exposure variables, we performed categorical analyses in which we compared subjects in each exposure quartile with those in the lowest quartile and tested for dose response. We also examined the outcomes both collectively and separately by subcategories, including study region, race, poverty, insurance type, infant sex, maternal age, parity, delivery type and method, and health conditions (diabetes for preeclampsia and preeclampsia for preterm birth).

Results

Descriptive statistics. Most mothers were non-Hispanic white or Hispanic (Table 1). The prevalence of preeclampsia was higher among PTD women compared with non-PTD women (12% vs. 2%) and among African-American women compared with other races (4% vs. 3%). Mild, severe, and HELLP syndrome accounted for 75%, 18%, and 7% of the preeclampsia cases, respectively. The prevalence of PTD was higher among male infants than among female infants (9% vs. 8%) and in African-American women than in other races (13% vs. 7–9%). Spontaneous delivery accounted for 79% of all births and occurred in 87% of preterm births and 78% of term births. The poverty rate in our study region was higher than the national average (14% vs. 11% based on 2000 Census data) (U.S. Census Bureau 2004).

Average air pollution exposures derived from the CALINE4 model for each pregnancy period and during the entire pregnancy were similar and moderately to strongly correlated (Table 2). CALINE4-estimated average monthly (over all subjects in each calendar month) NO_x exposures showed a clear seasonal trend, with higher exposures in the cool season (average of 10.8 ppb in December) and lower exposures in the warm season (average of 5.8 ppb in June), and we observed a very similar monthly trend for $PM_{2.5}$. The estimated concentrations were much lower than those measured at three ambient monitoring stations in the area (e.g., annual mean of 57.0 ppb NO_x), likely because our model estimates were for local traffic-generated emissions only. As expected, the modeled NO_x and $PM_{2.5}$ exposures were highly correlated (correlation coefficient $r = 0.91$) in every pregnancy trimester, because the two pollutants are emitted by the same source: local traffic.

Regression analyses. Because of only slight variations in exposures and effect estimates in different pregnancy periods [see Supplemental Material, Tables 1 and 2 (doi:10.1289/ehp.0800334.S1)], we present all regression results based on exposure during the entire pregnancy period. We found positive associations of preeclampsia and preterm birth with entire-pregnancy exposure to traffic-related air pollution (Table 3). An 11% increase was observed in adjusted risk of preeclampsia per IQR increase of entire-pregnancy NO_x. Preeclampsia results were the same for modeled $PM_{2.5}$ exposures. Overall, we observed somewhat stronger increases in risk of preterm birth with increases in modeled NO_x than with modeled $PM_{2.5}$. The effect of exposure tended to be stronger for VPTD (25% increase in risk per IQR increase in NO_x) than for PTD considered as a whole (6% increase in risk per IQR increase in NO_x).

Stratified analyses for preeclampsia and preterm birth were conducted [see Supplemental Material, Tables 3–6 (doi:10.1289/ehp.0800334.S1)]. We found greater impacts of traffic-related air pollution on preeclampsia and VPTD for women ≥ 40 years of age and in women < 20 years of age when giving birth, although 95% CIs overlapped to a large degree. We observed a higher risk of preeclampsia from local traffic-generated air pollution exposure among privately insured women than among women on public or government-sponsored insurance [for entire-pregnancy NO_x: interquartile OR (IOR) = 1.12; 95% CI, 1.06–1.18, vs. IOR = 1.04; 95% CI, 0.96–1.13]. Closer inspection, however, showed that this was mostly driven by the high percentage (83%) of older women (> 40 years of age) using private insurance (for > 40 age group: IOR = 1.44; 95% CI, 1.22–1.69; ≤ 40 age group:

Table 1. Descriptive statistics of infants and mothers in our study in south Los Angeles County and Orange County, California, from 1997 to 2006 ($n = 81,186$).

Variable	Measure
Mother's age (mean ± SD)	30.0 ± 6.2
Mother's race (%)	
African American	8.8

Table 2. Pollutant averages and Pearson's correlation coefficients for pollutants by pregnancy period.

					Pearson correlation coefficient							
					Entire pregnancy		First trimester		Second trimester		Third trimester	
Trimester	Pollutant	Mean[a]	IQR	SD	NO_x	$PM_{2.5}$	NO_x	$PM_{2.5}$	NO_x	$PM_{2.5}$	NO_x	$PM_{2.5}$
Entire pregnancy	NO_x	7.23	5.65	5.22	1.00							
	$PM_{2.5}$	1.82	1.35	1.33	0.90	1.00						
First trimester	NO_x	7.45	6.17	5.68	0.91	0.83	1.00					
	$PM_{2.5}$	1.83	1.44	1.37	0.84	0.94	0.91	1.00				
Second trimester	NO_x	7.29	6.02	5.57	0.97	0.87	0.85	0.79	1.00			
	$PM_{2.5}$	1.83	1.42	1.36	0.89	0.98	0.80	0.91	0.91	1.00		
Third trimester	NO_x	7.14	5.88	5.54	0.91	0.83	0.71	0.68	0.85	0.79	1.00	
	$PM_{2.5}$	1.84	1.43	1.39	0.85	0.95	0.70	0.82	0.79	0.90	0.91	1.00

[a]Units are parts per billion for NO_x and micrograms per cubic meter for $PM_{2.5}$.

Table 3. Crude and adjusted ORs per IQR increase[a] in traffic-related air pollutions for preeclampsia and preterm, moderate preterm, and very preterm birth.

Condition	No. of cases	Pollutant	Crude IOR (95% CI)	Adjusted[b] IOR (95% CI)
Preeclampsia	2,442	NO_x	1.15 (1.10–1.19)	1.11 (1.06–1.16)
		$PM_{2.5}$	1.13 (1.09–1.17)	1.11 (1.06–1.15)
PTD (< 37 weeks)	6,712	NO_x	1.12 (1.09–1.15)	1.06 (1.03–1.09)
		$PM_{2.5}$	1.09 (1.06–1.11)	1.03 (1.01–1.06)
MPTD (< 35 weeks)	2,749	NO_x	1.22 (1.18–1.26)	1.13 (1.09–1.18)
		$PM_{2.5}$	1.15 (1.11–1.19)	1.07 (1.03–1.12)
VPTD (< 30 weeks)	775	NO_x	1.32 (1.25–1.41)	1.25 (1.17–1.33)
		$PM_{2.5}$	1.23 (1.16–1.31)	1.18 (1.10–1.26)

[a]Based on entire-pregnancy exposure. IQR was 5.65 ppb for NO_x and 1.35 μg/m^3 for $PM_{2.5}$. [b]Adjusted for maternal age, maternal race/ethnicity, parity, prenatal care insurance type, poverty, and season of conception in all models. Additionally adjusted for pyelonephritis in PTD, MPTD, and VPTD models, and for diabetes in preeclampsia models.

IOR = 1.09; 95% CI, 1.03–1.16; based on entire-pregnancy NO_x) versus public or government-sponsored insurance (for > 40 age group: IOR = 0.93; 95% CI, 0.56–1.54; for ≤ 40 age group: IOR = 1.05; 95% CI, 0.97–1.14; based on entire-pregnancy NO_x). We observed no significant differences in effect estimates by study region, race/ethnicity, poverty, infant sex, parity, delivery type (spontaneous vs. nonspontaneous), delivery method (vaginal vs. cesarean section), diabetes status (for preeclampsia), and preeclampsia (for preterm birth).

Preeclampsia risk increased with quartiles of modeled NO_x and $PM_{2.5}$ exposures, and the increase was consistent with a linear dose response for NO_x (Figure 1). We observed a 33% (OR = 1.33; 95% CI, 1.18–1.49) and 42% (OR = 1.42; 95% CI, 1.26–1.59) increase in risk of preeclampsia for women in the highest NO_x and $PM_{2.5}$ entire-pregnancy exposure quartiles, respectively. We observed increasing risks with increasing quartiles of exposure to modeled NO_x and $PM_{2.5}$ and all preterm birth outcomes, yet the pattern was not always linear with dose (Figure 2). We observed a 128% (OR = 2.28; 95% CI, 2.15–2.42) and 81% (OR = 1.81; 95% CI, 1.71–1.92) increase in risk of VPTD for women in the highest NO_x and $PM_{2.5}$ entire-pregnancy exposure quartiles, respectively. The dose–response relationships from the quartile categorical analyses were consistent with what we observed from smoothing curves of dose response [see Supplemental Material, Figure 2 (doi:10.1289/ehp.0800334.S1)].

Discussion

There is growing interest in exploring the possible effects of ambient air pollution on fetal and perinatal development because the growing fetus may be particularly susceptible to the toxic effects of air pollutants (Maisonet et al. 2004; Mone et al. 2004; Pinkerton and Joad 2006). Our study contributes new results based on exposure data from a dispersion model for local traffic-generated air pollutants and preeclampsia. To our knowledge, this is the first study to show a positive association between exposure to local traffic-generated pollutants at the birth residence and the development of preeclampsia during pregnancy. We also found that the risk of premature birth increases with exposure to local traffic-generated pollutants, and this risk was strongest for VPTD followed by MPTD and PTD. This is important because postnatal health impairments are greatest for the children born most premature (Doyle 1995, 2008).

The present study had two major advantages over previous studies examining traffic air pollution and birth outcomes. First, we modeled air pollution exposures from local traffic sources (within 3 km) using a comprehensive traffic database and a well-established dispersion model that better characterizes spatiotemporal variability in exposure than that used in most previous studies. Two exceptions are recent studies from Munich, Germany (Slama et al. 2007), and Vancouver, Canada (Brauer et al. 2008), that employed temporally adjusted LUR models. However, because the LUR models were based on ambient air measurement data, they estimated total ambient air pollutant concentrations with contributions from many sources other than local traffic emissions. Thus, these exposure estimates only partially represent local traffic-generated air pollutants. The amount of total estimated ambient pollution that is contributed from traffic may vary according to location in LUR models. In addition, LUR models may not perform well in predicting temporal variations of exposures because they are mostly built relying on one to four purpose-designed monitoring windows of 7 to 14 days, with or without further temporal adjustment using ambient monitoring station data (Hoek et al. 2008).

The second major advantage is that the present study used detailed individual-level clinical data (e.g., chronic hypertension, pyelonephritis, diabetes, heart disease), allowing us to evaluate the impact of these clinical parameters on air pollution effect estimates. But more important, we were able to employ more accurate gestational age information to classify preterm birth than most previous air pollution studies that relied on birth certificates. Gestational ages on birth certificates are usually based on first day of last menstrual period, which leads to misclassification of gestational age due to poor recall, postconception bleeding, or menstrual irregularities (Dietz et al. 2007; Kline 1989; Lynch and Zhang 2007). One the other hand, gestational age estimated by ultrasound measurements alone may induce systematic errors and inflate the risk of PTD (Olsen and Basso 2005). More than 99% of our subjects obtained prenatal care early in pregnancy, which ensured that their estimated conception date was based on a combination of last menstrual period and early ultrasound dating. Moreover, our preeclampsia data were based on hospital records of clinical diagnoses, probably more accurate than the preeclampsia data reported on birth certificates that may only record extreme or severe preeclampsia cases.

We estimated only local traffic-generated air pollution exposure in this study, whereas

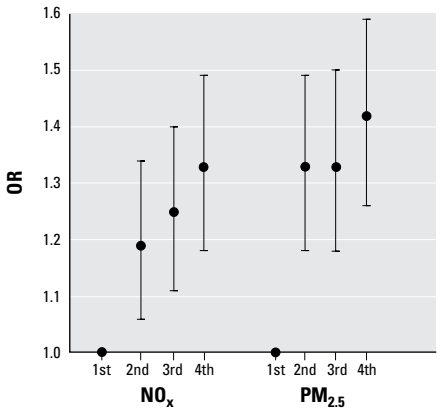

Figure 1. Adjusted ORs (95% CIs) for preeclampsia by entire-pregnancy exposure quartile (adjusted for maternal age, maternal race/ethnicity, parity, prenatal care insurance type, poverty, diabetes, and season of conception).

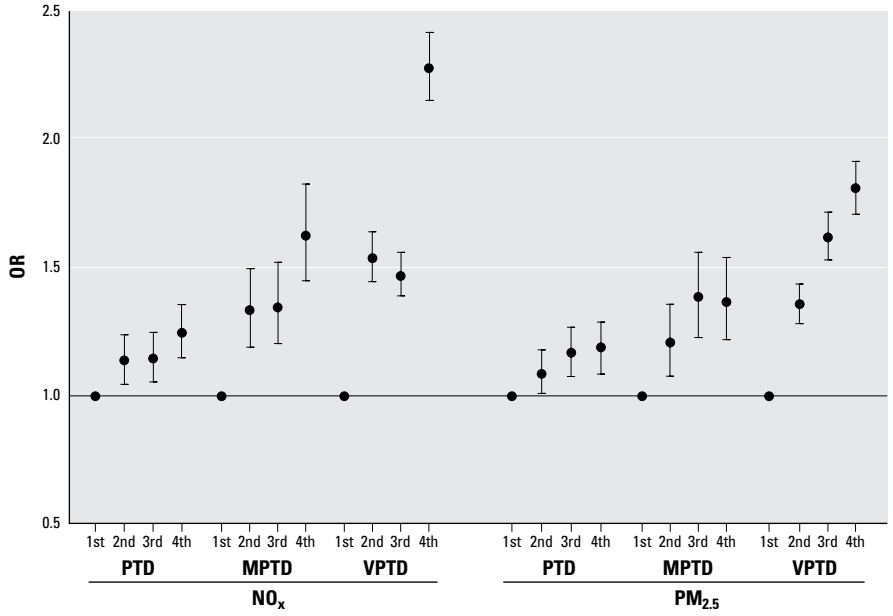

Figure 2. Adjusted ORs (95% CIs) for PTD, MPTD, and VPTD by entire-pregnancy exposure quartile (adjusted for maternal age, maternal race/ethnicity, parity, prenatal care insurance type, poverty, pyelonephritis, and season of conception).

most previous studies based on ambient or modeled total concentration data (e.g., carbon monoxide and NO_x) examined contributions from not only local traffic but also pollutants transported from upwind regions and from other sources. Local traffic emissions may differ from aged pollutants from long-range transport in terms of chemical composition and particle size distribution. Therefore, our estimated effect sizes for different outcomes may not be directly comparable to those from other air pollution studies.

The only results ever reported for air pollution and preeclampsia relied on CO concentrations measured at the nearest ambient air monitor to residence (Woodruff et al. 2008) or CO and $PM_{2.5}$ concentrations estimated using linear regression models at each residence (Rudra and Williams 2006). Rudra and Williams (2006) observed a 49% increase in preeclampsia risk (95% CI, 0.76–2.90) for third- versus first-tertile average CO exposures during the month of conception and the following 3 months among women in Seattle, Washington, and Woodruff et al. (2008) reported an 8% increase in preeclampsia risk (95% CI, 1.02–1.14) for the highest versus the lowest entire-pregnancy CO exposure quartile in Californian women. In our study, women exposed at the highest quartile of modeled entire-pregnancy $PM_{2.5}$ experienced approximately 40% higher risk of developing preeclampsia compared with women in the lowest quartile of exposure. We also noted a slightly higher risk of preeclampsia from local traffic-generated air pollution exposure among privately insured women. This might have been attributable to the high percentage (83%) of older women (> 40 years of age) using private insurance, as mentioned above, or may result from more accurate diagnosis of preeclampsia in privately compared with publicly insured women. Also, older pregnant women might be especially vulnerable to the effects of toxins such as air pollutants.

Our preterm birth results are consistent with results from previous birth outcome studies in the literature. In addition, the preterm birth results were similar using separate models for the three nonexclusive preterm outcomes compared with multilogit models that captured the relatedness of the three outcomes [see Supplemental Material, Table 7 (doi:10.1289/ehp.0800334.S1)]. We estimated a 6% increase in risk of PTD per IQR in modeled entire-pregnancy NO_x exposure and a 25% increased risk of PTD for mothers in the highest NO_x exposure quartile. Wilhelm and Ritz (2003) previously reported a 10–20% increase in the risk of PTD in mothers exposed to high levels of local traffic-generated air pollution in Southern California, based solely on residential distance-weighted traffic density. Following up on this first study, they conducted a nested case–control study within another birth cohort in Los Angeles County, California, and found PTD to be approximately 20% higher in mothers with first trimester CO exposure > 1.25 ppm (Ritz et al. 2007). A study from Taiwan estimated a 30% increased risk of PTD for mothers living within 500 m of a major freeway (Yang et al. 2003). A more recent study from Vancouver, Canada, reported no consistent association of PTD (< 37 weeks) with any of the pregnancy air pollution exposure metrics (including LUR measures) except inverse distance–weighted $PM_{2.5}$ concentration during the entire pregnancy (OR = 1.06; 95% CI, 1.01–1.11; per 1-$\mu g/m^3$ increase in $PM_{2.5}$) (Brauer et al. 2008). Similar to our findings, risk increased when they further restricted PTD to < 30 weeks of gestation (for $PM_{2.5}$ exposure: OR = 1.13; 95% CI, 0.92–1.39; for NO_x exposure: OR = 1.26; 95% CI, 1.08–1.47).

We found the risk of preeclampsia and VPTD due to modeled NO_x and $PM_{2.5}$ exposure from traffic to be greater in the youngest (< 20 years of age) and the oldest (≥ 40 years of age) age groups, consistent with the preterm birth results of a study in Los Angeles County, California (Ponce et al. 2005). Two U.S. studies, one conducted in Arizona and North Dakota (Ahluwalia et al. 1997) and the other in California (Windham et al. 2000), have also reported a stronger impact of environmental tobacco smoke (ETS) on preterm births among older (≥ 30 years of age) compared with younger (< 30 years of age) mothers, further suggesting possible differences in vulnerability by maternal age.

There were several limitations in the present study. We likely reduced exposure measurement error for primary traffic pollutants by using a dispersion model and a sophisticated traffic database versus relying on ambient measurements. However, the exposure estimates were based solely on the maternal address at time of birth. Mobility rates among pregnant women reported in the literature range from 12% (Fell et al. 2004) to 35% (Brauer et al. 2008). Ritz et al. (2007) found that associations between air pollution exposures (estimated via nearest air monitor) during pregnancy and preterm birth did not change or slightly strengthened when restricting analyses to women who did not move during pregnancy. The estimates of exposures in the present study, however, may have been affected more strongly by residential mobility because they are more spatially resolved than in previous studies. Second, our exposure estimates were based only on residential addresses, ignoring other microenvironments (e.g., workplace, commuting) that might be important for personal exposures. Ritz et al. (2007) reported associations between monitor-based estimates of air pollution exposure during pregnancy and PTD to be greater for women who did not work (and for whom a residence-based measure of exposure presumably is more accurate) than for women who worked outside their homes.

Another potential source of bias is residual confounding due to risk factors we were unable to account for in our analyses (e.g., maternal smoking, ETS, stress, and nutrition). Ritz et al. (2007) collected detailed survey data postnatally on risk factors not reported on birth certificates and assessed the influence of these potential confounding factors on air pollution effect estimates for preterm birth. Adjustment for covariates on birth certificates exhibited the strongest influence on the pollutant effect estimates, whereas additional adjustment for a large number of survey covariates (e.g., occupation, income, maternal smoking and ETS, alcohol drinking) changed the effect estimates by < 5%. This confirmed that for pollutants that change with season and are averaged over short time intervals (pregnancy months or trimesters), behavioral factors that do not change seasonally are unlikely to be confounders. Compared with ambient measurements of total pollutant concentrations, however, the major contrast in the CALINE4-modeled exposure was spatial rather than temporal. Therefore, residual confounding cannot be ruled out in these primarily spatially based exposure measures.

It is also uncertain to what degree the dispersion model we used represents pollutant species released only by traffic. Comparing modeled and measured concentrations, we observed reasonable agreement between CALINE4-modeled and measured 2-week average NO_2 concentrations at 260 residences in six communities participating in the Southern California Children's Health Study, with an R^2 ranging from 0.3 to 0.9 (Gauderman et al. 2005; Jerrett 2006). Relatively high correlations ($n = 14$; $R^2 = 0.76$) were found between CALINE4-modeled and measured monthly average concentrations of NO_x at nine monitoring stations in the Long Beach area in November 2007 and/or April 2008 (Wu J, Lurmann F, Avol E, unpublished data). The R^2 for daily estimates ranged from 0.19 to 0.81 (mean = 0.36) among the nine stations (Wu J, Lurmann F, Avol E, unpublished data). Thus, we expect that longer-term exposure estimates (monthly, trimester, and entire-pregnancy averages) derived from CALINE models closely reflect residential exposure to local traffic-generated pollutants because traffic counts and mixing heights are based on long-term, annual, or seasonal average observations.

Both modeled $PM_{2.5}$ and NO_x were associated with PTD and preeclampsia, but this should not be interpreted to mean that these pollutants are necessarily causative for these

adverse outcomes; rather, they could be acting as surrogates of traffic exhaust, which is a complex mixture of hundreds of toxic components (Kim et al. 2008; Singer et al. 2004). There is evidence that UFP number concentrations may be a more appropriate metric than gas or particle mass concentrations when evaluating health risk from traffic-related air pollution (Oberdörster et al. 2005). UFPs may be causal agents for the observed health effects due to their high pulmonary deposition efficiency, and their orders of magnitude higher number concentration and surface area that allows them to carry larger concentrations of adsorbed or condensed toxic air pollutants (e.g., oxidant gases, PAHs, and transition metals) to the fetus and the placenta (Oberdörster et al. 2005). UFPs contain a significant amount of PAHs, which have been linked to various measures of intrauterine growth retardation in studies in New York State (Choi et al. 2006, 2008; Perera et al. 2003, 2004), Krakow, Poland (Choi et al. 2006), and industrial areas of the Czech Republic (Dejmek et al. 2000). Yet, little is known to date about the etiologic role that UFPs and PAHs may play for preterm birth and preeclampsia.

Several hypotheses have been postulated to explain how air pollution may trigger PTD. Toxic compounds in traffic-generated air pollutants may interfere with placental development and subsequent nutrient and oxygen delivery to the fetus (Dejmek et al. 2000). Another potential mechanism of developmental toxicity is through the activation of the oxidative stress pathway. PTD may be triggered by an abnormal production or an early activation of cytokines favoring inflammation, even though increasing concentrations of inflammatory cytokines may be part of the body's preparation for normal parturition (Engel et al. 2005; Keelan et al. 2003).

The mechanisms that initiate preeclampsia in pregnant women have been elusive (Mutter and Karumanchi 2008; Shah 2007). Pathology studies show that an abnormal development of an ischemic placenta with a high-resistance vasculature contributes to the development of preeclampsia. Endothelial dysfunction plays a central role in the pathogenesis of the syndrome. Multiple interconnected pathways linked to endothelial dysfunction involve oxidative stress, cytokine release, and a generalized intravascular inflammatory response (Baumwell and Karumanchi 2007). Exposure to traffic-related pollutants, such as UFPs and PAHs, can cause oxidative stress (Li et al. 2003; Nel et al. 2001; Oberdörster et al. 2005) and endothelial dysfunction (Tornqvist et al. 2007). Such exposure could thus contribute to the cardiovascular complications of preeclampsia as well as PTD (Gitto et al. 2002).

Conclusions

Exposures to local traffic-generated air pollution modeled with CALINE4 for the entire pregnancy elevated the risk of preterm birth and preeclampsia in Southern California women. A 42% increased risk of preeclampsia was observed for the highest quartile of modeled traffic-related $PM_{2.5}$ exposure during the entire pregnancy. For preterm birth, the exposure–response relation was strongest for VPTD with potentially serious consequences for the newborn. These results provide further evidence that traffic-related air pollution is associated with adverse reproductive outcomes.

ABSTRACT

Background: Low birth weight (LBW, <2500 g) has been associated with exposure to air pollution, but it is still unclear which sources or components of air pollution might be in play. The association between ultrafine particles and LBW has never been studied.
Objectives: To study the relationships between LBW in term born infants and exposure to particles by size fraction, source and chemical composition, and complementary components of air pollution in Los Angeles County (California, USA) over the period 2001–2008.
Methods: Birth certificates ($n=960{,}945$) were geocoded to maternal residence. Primary particulate matter (PM) concentrations by source and composition were modeled. Measured fine PM, nitrogen dioxide and ozone concentrations were interpolated using empirical Bayesian kriging. Traffic indices were estimated. Associations between LBW and air pollution metrics were examined using generalized additive models, adjusting for maternal age, parity, race/ethnicity, education, neighborhood income, gestational age and infant sex.
Results: Increased LBW risks were associated with the mass of primary fine and ultrafine PM, with several major sources (especially gasoline, wood burning and commercial meat cooking) of primary PM, and chemical species in primary PM (elemental and organic carbon, potassium, iron, chromium, nickel, and titanium but not lead or arsenic). Increased LBW risks were also associated with total fine PM mass, nitrogen dioxide and local traffic indices (especially within 50 m from home), but not with ozone. Stronger associations were observed in infants born to women with low socioeconomic status, chronic hypertension, diabetes and a high body mass index.
Conclusions: This study supports previously reported associations between traffic-related pollutants and LBW and suggests other pollution sources and components, including ultrafine particles, as possible risk factors.

1. Introduction

Intrauterine growth restriction and resulting low birth weight (LBW, defined as birth weight less than 2500 g) have been associated with increased risks of chronic diseases in later life such as the metabolic syndrome, type 2 diabetes mellitus and cardiovascular diseases, (Chernausek, 2012), but also wheezing and asthma in childhood (Caudri et al., 2007). Air pollution induces oxidative stress, inflammation (Schlesinger et al., 2006) and hemodynamic changes, which are suspected to impair oxygen and nutrient transport to the fetus, and in turn, intrauterine growth (Kannan et al., 2006). Results from a growing number of epidemiological studies do suggest that exposure of pregnant women to air pollution may result in higher risks of LBW (Dadvand et al., 2013; Pedersen et al., 2013; Stieb et al., 2012).

Abbreviations: LBW, low birth weight; IQR, inter-quartile range; OR, odds ratios; CI, confidence intervals; $PM_{2.5}$, particulate matter of less than 2.5 μm in aerodynamic diameter; $PM_{0.1}$, particulate matter of less than 0.1 μm in aerodynamic diameter; EBK, empirical Bayesian kriging; UCD_P, University of California Davis/CIT_Primary chemical transport model; CTM, chemical transport models; NO_2, nitrogen dioxide; O_3, ozone; FRC, Functional Road Classes; BMI, body mass index; EC, elemental carbon; OC, organic carbon; LUR, land use regression; PAH, polycyclic aromatic hydrocarbons

However, associations between air pollution exposure and LBW differ widely depending on study settings and designs (Brauer et al., 2008; Laurent et al., 2013).

It is suspected that the different definitions of air pollution metrics partly contribute to discrepancies in the literature (Dadvand et al., 2013). Characterizing exposure to air pollution is challenging and the different exposure assessment methods present advantages and limitations (e.g., in terms of temporal and spatial resolutions). Consequently, assessing the consistency of epidemiological results obtained using complementary exposure metrics can be useful to draw more informed conclusions. For instance, in Los Angeles positive associations were observed between the risk of preeclampsia and ambient nitrogen oxides concentrations, whether these concentrations were estimated by monitoring station measurements, land use regression or deterministic modeling, which strengthened confidence in this finding (Wu et al., 2011b).

Particulate matter (PM) has various core compositions and absorbs transition metals, polycyclic aromatic hydrocarbons (PAHs) and other organic compounds, that are able to generate oxidative stress and inflammation to various extents (Schlesinger et al., 2006; Delfino et al., 2010). Differences in PM composition have therefore been hypothesized to modify the relationship between total PM mass and LBW (Ebisu and Bell, 2012). Notable spatial contrasts in PM composition have been documented across the U.S. (Bell et al., 2007). However, few studies investigated the relation between PM composition and birth weight (Bell et al., 2010, 2012; Darrow et al., 2011; Ebisu and Bell, 2012), probably because of the scarcity of particle speciation data.

There are also open questions, of direct relevance to policy, on the sources of air pollution most likely to generate detrimental effects on pregnancy outcomes. Recent publications have suggested a possible influence of primary emissions from traffic on LBW (e.g.: Laurent et al., 2013; Wilhelm et al., 2012). Such an influence is biologically plausible since some components of primary traffic emission (e.g.: organic compounds such as PAHs, elemental carbon, trace metals) promote systemic inflammation and decrease antioxidant enzyme activity (Delfino et al., 2010). The possible influence of other sources of air pollution (e.g.: wood burning and meat cooking, that notably generate PAHs and other organic compounds) has also been suggested (Boy et al., 2002; Wilhelm et al., 2012). However, only one study attempted to assess simultaneously the relative contributions from different sources to the risk of LBW (Wilhelm et al., 2012), probably since results from source apportionment methods (e.g.: Chemical Mass Balance or Positive Matrix Factorization) are relatively rare and remain site-specific.

Chemical transport models (CTMs) have been used to address issues of the lack of source information and measurement scarcity for certain air pollutants (Hu et al., 2014a). For instance CTMs can predict the detailed size and chemical composition of primary PM with reasonable temporal and spatial resolution, while keeping track of source information. This approach can also apply to particles of certain size fractions for which direct measurement data are usually too rare to be directly usable in epidemiological studies, such as particles less than 0.1 μm in aerodynamic diameter ($PM_{0.1}$) (Abernethy et al., 2013). Concerns exist about the toxicity of $PM_{0.1}$ due to their specific properties (potential for translocation into the blood or other organs than lung, large number concentration and surface-to-volume ratio) (Knol et al., 2009). To the best of our knowledge, the relationship between birth weight and $PM_{0.1}$ has never been studied.

This work aimed at studying the relationships between air pollution and LBW in term born infants in Los Angeles County, California. It extends previous research on this topic, by using spatiotemporal chemical transport modeling of primary particles by source and composition and by studying $PM_{0.1}$ exposure. It also makes use of more commonly used air pollution metrics such as interpolated measurement data, traffic indices and proximity to roads. This allows for comparison of results according to complementary exposure metrics for traffic-related air pollution.

2. Methods

2.1. Study population

Birth certificate records for all births occurring from January 1, 2001 to December 31, 2008 to women residing in Los Angeles County ($n=1{,}203{,}782$) were obtained from the Health Information and Research Section at the California Department of Public Health. Multiple births ($n=35{,}213$) were excluded along with infants with recorded birth defects or unknown birth defects status ($n=3353$ and $n=398$, respectively). Births with missing information for gestational age ($n=62{,}724$), or implausible combinations of birth weight and gestational age (Alexander et al., 1996) were also excluded ($n=4995$). Further, infants born before 260 or after 308 estimated days of gestation ($n=141{,}485$ and $n=22{,}839$ respectively) were excluded (Bell et al., 2010). Several exclusion criteria overlapped for certain births, leaving 960,945 births for analyses.

Maternal addresses of residence recorded on birth certificates were geocoded using the University of Southern California GIS Research Laboratory geocoding engine (Goldberg et al., 2008), which geocoded births at the centroid of tax parcels whenever feasible. In total, we had 53% of addresses geocoded to a specific parcel, 42.5% using address range interpolation,[1] 4.5% at the Zip code centroid level, and 0.05% at the city centroid.

2.2. Air pollution metrics

2.2.1. Chemical transport modeling

The University of California Davis/CIT_Primary (UCD_P) chemical transport model (Hu et al., 2014a) estimated primary ground-level PM element concentrations across densely populated areas of California including Los Angeles County at a 4 km 4 km grid resolution for particles ranging from 0.01 to 20 μm from approximately 900 sources. In the present study, the simulated PM concentrations were calculated for two particle size fractions ($PM_{2.5}$ and $PM_{0.1}$) for the period of 2000–2006. The UCD_P model was developed to track primary PM (emitted directly from sources) through a simulation of emission, advection, diffusion and deposition. The detailed descriptions of the model and its validation are the purpose of other publications (Hu et al., 2014a, 2014b), but its main components are summarized below.

Size and composition resolved particle emissions were derived from a library of primary particle source profiles measured during actual source tests. Gridded emissions were prepared using the raw emissions inventory provided by the California Air Resources Board (Hu et al., 2014a). Meteorological inputs were prepared using the Weather Research and Forecast (WRF) model version 3.1 (Skamarock et al., 2008). Published papers describe the bulk advection and turbulent diffusion algorithm (Kleeman and Cass, 2001), the dry deposition approach (Kleeman et al., 1997), the vertical advection scheme (Hu et al., 2010), and the wet deposition scheme (Mahmud et al., 2010) used in the model. Every source with a unique emissions inventory code (EIC) in the emissions database was tracked separately through model simulations. In the present study, we defined seven broad source categories, namely gasoline, diesel, shipping, high sulfur combustion sources (including aircraft, electricity generation, petroleum refining and other industries), commercial meat cooking, wood burning, and other sources. The mass and density of size-resolved PM were tracked during model calculations, with composition profiles applied during post-processing of results. UCD_P only tracked primary PM and did not account for the formation of secondary PM produced by chemical reactions in the atmosphere, which might have different health effects (Delfino et al., 2010) and will be studied in future works.

Women living in each of the 448 model grid cells covering Los Angeles County (see Appendix Fig. A.1) at the time of delivery were assigned daily concentrations estimated for the corresponding cell, which were then averaged for specific pregnancy periods (entire pregnancy, 1st, 2nd or 3rd trimester).

2.2.2. Monitoring station measurements

Measurements from government monitoring stations for the period 2000–2008 were obtained from the California Air Resources Board for total $PM_{2.5}$, nitrogen

[1] If no parcel match could be found for an address, an approximate location for this address was determined by using the address range for the matched street segment – the location was determined by computing where the address would fall as a proportion of the total address range associated with the appropriate side of the street segment. This proportion was then applied to the total length of the street segment (Goldberg et al., 2007).

dioxide (NO_2) and ozone (O_3). Only results from filter-based measurements, generally conducted every 3 or 6 day, were included for $PM_{2.5}$. Hourly NO_2 and O_3 measurements were converted to daily means using a criterion of 75% daily data completeness at 24-h basis. Only data for the 10 AM–6 PM time windows were used to calculate daily means for O_3. Monthly averages for pollutants were then calculated for stations with more than 75% days of valid data in a month. These monthly averaged concentrations were spatially interpolated between stations using an empirical Bayesian kriging (EBK) model (Pilz and Spock, 2007) implemented in ArcGIS 10.1 (ESRI, Redlands, CA). EBK accounts for the uncertainty of semivariogram estimation by a process of subsetting and simulations. Due to a high computational cost, we conducted 100 variogram simulations for monthly averaged concentrations only. Pollutant surface predictions and their associated variance (reflecting the uncertainty in variogram estimation and subsequent predictions) were generated for 200 m 200 m grids. The EBK was applied for the entire California, where the number of available monitors with valid measurements for each pollutant varied during the study period. The ranges of available monitors per month were 75–98 for $PM_{2.5}$, 151–182 for O_3 and 94–109 for NO_2. Our study region (Los Angeles County) had 5–11 monitors for $PM_{2.5}$, 12–16 for O_3, and 11–16 for NO_2 (see Appendix Fig. A.1). Final pollutant concentration estimates were calculated for each mother by weighing monthly average concentrations by the number of days of each month during pregnancy or specific pregnancy trimesters (Wu et al., 2011b).

2.2.3. Traffic and roadways

Traffic indicators are crude proxies for emission sources of traffic-related pollutants (Wilhelm and Ritz, 2003) but might capture - though imperfectly - small-scale variations in primary traffic emissions (e.g.: $PM_{0.1}$ EC, trace metals) which were modeled only at coarser resolutions in this study. Traffic densities within circular buffers of different sizes (radii from 50 m to 350 m with a 100 m increment) centered on maternal homes were calculated based on 2002 annual average daily traffic counts (AADT) data from the California Department of Transportation (CALTRANS, 2012). To estimate traffic density, AADT on each road segment was weighted by the length of this same road segment within the buffer. These traffic densities based on 2002 AADT were then scaled to other years based on temporal trends in total vehicle miles traveled in Los Angeles County (CALTRANS, 2013).

TeleAtlas street data (ESRI, 2010) were used to calculate the distance from each maternal home to the nearest freeway or highway (defined by categories of Functional Road Classes(FRC) A0–A3), and the nearest major road (FRC A0–A5). The same road data were used to calculate the total length of major road segments within 50–350 m around homes.

2.3. Statistical analyses

Generalized additive models as implemented in the "mgcv" package (version 1.7-18) of the R environment (version 2.15.1) were used to study the relationships between air pollution metrics and term LBW. A logistic link function with a quasi-binomial distribution was used, given observed under-dispersion (scale parameter ≤ 0.2). In the main models, maternal race/ethnicity, educational level, parity, the trimester of pregnancy during which primary care began and infant's gender were adjusted for using categorical variables. Maternal age, length of gestation and median household income by Census Block Group (U.S. Census Bureau, 2004) were adjusted for using smoothing splines, given their J-shape relationships with LBW. For pollutant concentrations interpolated by EBK, regressions were weighted by the inverse variance of pollutant predictions. For temporally-varied exposure, we conducted analyses for entire pregnancy exposures, then for each pregnancy trimester. We explored the shapes of the relationships between air pollution metrics and LBW using smoothing splines, and generally observed no major departure from linearity (see Appendix Fig. A.2). We therefore introduced most air pollution metrics as linear terms in the models and then report related odds ratios (OR) for LBW per an inter-quartile range (IQR) in air pollution metrics, with 95% confidence intervals (CI). Distance to roadway was analyzed using dichotomous indicators for living or not living within certain distances (i.e. 50, 100, 150 m) from roads.

In sensitivity analyses, we examined the effects of further adjustment for population density, diabetes (pre-pregnancy and gestational combined), chronic hypertension and preeclampsia. We explored the influence of controlling for both seasonal and long-term temporal trends by adjusting for a smoothed function of the day of conception, with four degrees of freedom per year (Barnett et al., 2011). In the subset of infants born in 2007 and 2008, we examined the effects of adjustment for maternal height, body mass index (BMI) at the beginning of pregnancy and weight gain during pregnancy, which were only recorded on birth certificate during these two years. Further, we explored the influence of geocoding accuracy, by analyzing the subgroup of births geocoded at the exact parcel centroid.

We investigated potential effect modifications by maternal race/ethnicity, education, median block group income, hypertension, diabetes (pre-pregnancy and gestational combined) and preeclampsia. In the 2007–2008 births subsets, effect modification by maternal BMI at the beginning of pregnancy was explored, using categories defined by Abrams and Parker (1988) (see Table 1), with and without adjusting for maternal height and weight gain during pregnancy. As the inter-quartile range in exposure differs between subgroups defined by categories of potential effect modifiers, we present all results of subgroup analyses standardized to the IQR in exposure observed for the entire population.

This study has been approved by the Institutional Review Board of the University of California, Irvine.

3. Results

The mean birth weight among term born infants was 3390.1 g (standard deviation: 459.8 g) and 22,420 (2.33%) of them had a

LBW. Maternal educational level was missing for 1.4% of the subjects (Table 1). The proportion of missing data was even lower for other variables, except for maternal height, weight at the beginning of pregnancy, and gestational weight gain (9.2%, 13.8%, and 15.3% respectively) in 2007–2008 data. The proportion of missing data for diabetes, chronic hypertension and preeclampsia is unknown – only the presence, but not the absence, of these diseases was explicitly recorded on birth certificates. The proportion of LBW by maternal characteristics, diseases and median income level follows the expected directions (Table 1).

Appendix, Table A.1 presents the mean and correlation of each exposure metric used in the study. Total $PM_{2.5}$ and NO_2 interpolated by EBK were strongly positively correlated, and both were negatively correlated with O_3. Total $PM_{2.5}$ was moderately correlated with primary $PM_{2.5}$ modeled by UCD_P ($R=0.49$) and was weakly correlated with traffic density, road length and distance to roads ($R \leq 0.20$). UCD_P predictions of primary PM from several sources were highly correlated with each other – gasoline and diesel ($R=0.96$), meat cooking and gasoline or diesel ($R=0.86$), mass from all sources and from sources classified as "other" ($R=0.96$ and 0.89 for $PM_{2.5}$ and $PM_{0.1}$ respectively). Gasoline and diesel contributed respectively to 8% and 21% of the total $PM_{2.5}$ primary mass, and to 12.5% and 24% of the total $PM_{0.1}$ primary mass. Contributions from meat cooking, wood burning, high sulfur sources and shipping were respectively around 15%, 8%, 6% and 3% for each PM fraction.

The correlations between primary $PM_{2.5}$ and $PM_{0.1}$ for the same source were above 0.87. The correlations between $PM_{2.5}$ and $PM_{0.1}$ for a same chemical species (contributions from all sources being summed) ranged from 0.67 to 1. Traffic density and road length were only slightly correlated with pollutant concentrations interpolated by EBK or with predicted primary $PM_{2.5}$ and $PM_{0.1}$ from all sources ($|R| \leq 0.23$). Correlations between road length and traffic density within a same buffer size ranged from 0.53 (50 m buffer) to 0.62 (350 m buffer). Distance to roadways was negatively but moderately correlated with all other exposure metrics ($|R| \leq 0.32$), except O_3 ($R=0.20$).

For the entire pregnancy exposure, a 2.5% increase in risk of term LBW was associated with an inter-quartile range increase in primary $PM_{2.5}$ or $PM_{0.1}$, for all sources summed. Significant associations of similar magnitudes were also observed for primary PM from each specific source, except shipping (Table 2). Gasoline was the PM source most strongly associated with LBW, followed by wood burning and meat cooking. Among the chemical species studied, increased LBW risk was associated with elemental and organic carbon (EC, OC), potassium, iron, manganese and nickel in both particle fractions. Increased LBW risk was also associated with titanium and copper in $PM_{2.5}$ and chromium in $PM_{0.1}$. Associations with UCD_P predictions were overall stronger for third trimester exposures (Appendix, Table A.2).

For EBK-interpolated measurements, we observed a significant increase in LBW risk for total $PM_{2.5}$, but not O_3 or NO_2 (Table 2). The OR for total $PM_{2.5}$ was of similar magnitude to that observed for primary $PM_{2.5}$ or $PM_{0.1}$ estimated by the UCD_P model. Trimester-specific results revealed patterns similar to those for the entire pregnancy period (Appendix, Table A.2). However, for the third trimester exposure only, a significantly increased LBW risk was associated with NO_2, whereas a significantly decreased risk was associated with O_3.

Small yet statistically significant increases in LBW risk were associated with increases in traffic density and total road length within 50 m buffers. For road length, an increased LBW risk was also significant for a 150 m buffer. Living within 50 m and 100 m of any major road was associated with a 6% (95% CI: 4–7%) and 3% (95% CI: 2–4%) increase in LBW risk respectively. The increase was 7% (95% CI: 1–13%) for living within 50 m of a freeway or highway (Table 2).

Adjustment for population density, diabetes, chronic hypertension, preeclampsia, maternal height, pre-pregnancy BMI or weight gain during pregnancy changed ORs by 1% or less (data not shown). The influence of adjustment for time of conception was also weak, except that for wood burning it yielded increased odds ratios, from about 2% to 5–6% increase in risk per IQR in exposure (Appendix Table A.3). Restricting analyses to births geocoded to the exact parcel centroid reduced the study population by half, but did not substantially change the distribution of maternal age, education or race/ethnicity. In this subgroup with the best geocoding accuracy, ORs remained positive and significant for primary PM from gasoline, diesel, meat cooking and all sources grouped, road length within 50 and 150 m buffers and living with 50 m of major roadway or freeways. Contrarily to the main analysis, traffic density within 150–350 m buffers but not 50 m was associated with increased LBW risk (data not shown).

For analyses stratified by maternal race/ethnicity, most significant associations between LBW and primary PM were observed in infants of Hispanic mothers (Appendix Table A.4). Increased risks associated with NO_2 were observed in infants of Hispanic and African Americans mothers, whereas increased risks associated with O_3 were observed in infants of White non-Hispanic mothers. A few unexpected significant decreases in risk were observed notably in infants of Asian mothers for PM, O_3 and NO_2, and of White non-Hispanic mothers for traffic density and road length in 250 and 350 m buffers.

For analyses stratified by maternal education, significant and generally stronger associations with EBK-interpolated $PM_{2.5}$ and NO_2 and with primary particles were observed for the lowest educational levels subgroups (Appendix Table A.5). For traffic and road indices, overall more significant increases in risk were observed in subgroups with higher education. However, statistical power was lower in the group with the lowest educational level. Analyses stratified by quartile of block group median income did not reveal any marked pattern (data not shown).

Stronger associations between LBW and air pollution were observed in women with than without chronic hypertension, for most exposure metrics considered (see Appendix Table A.6). Stronger associations were also observed in women with than without diabetes for ozone, traffic and road indexes, but patterns were less clear for other exposure metrics (Appendix Table A.7). No consistent pattern was observed by preeclampsia status (Appendix Table A.8). In 2007–2008 data, the risk of LBW associated with EBK-interpolated $PM_{2.5}$ consistently increased from the lowest to the highest pre-pregnancy BMI category. This pattern persisted after further adjustment for maternal diseases, height and weight gain (data not shown). No such pattern was observed for O_3 or NO_2 (Appendix Table A.9).

4. Discussion

This is one of the first studies relating term LBW with concentrations of primary particle by source and composition and to the best of our knowledge, the first study of $PM_{0.1}$ and LBW. The results show modest increases in the risk of LBW associated with primary $PM_{2.5}$ and $PM_{0.1}$ from all sources except shipping and with several chemical species (EC, OC, potassium, iron, manganese, chromium, nickel, copper and titanium) in primary PM. Increased LBW risks are also associated with total $PM_{2.5}$ interpolated by EBK, with NO_2 in the last pregnancy trimester, and with local traffic indicators. Several population subgroups with potentially higher susceptibility were identified – infants of mothers with a lower education, Hispanic ethnicity, diabetes, chronic hypertension, and a high BMI.

[a] IQR: inter-quartile range. Units are microgram per cubic meter for particles.
[b] OR: odds ratio estimated by generalized additive models adjusting for maternal race/ethnicity, education, parity, trimester primary care beginning, infant's gender, maternal age, length of gestation and median income by census Block Group
[c] CI: confidence interval

Long-term measurements for PM speciation or for $PM_{0.1}$ mass are very limited (Abernethy et al., 2013; Bell et al., 2007). Chemical transport modeling is an alternative approach to address the lack of measurement data and to link pollutant concentrations with specific sources. The resolution of 4 km 4 km grid cells is coarse as compared with, for instance, spatial variations of ultrafine particle number emitted by traffic sources (Karner et al., 2010). Still, this approach allowed reflecting spatial contrasts at broader scales, that would not be captured by central site monitors (Hu et al., 2014a), and allowed including all births in Los Angeles County, whether mothers were living close to a monitor or not.

Detailed discussions on uncertainties in UCD_P predictions associated with model inputs and treatment on various processes have been presented in Hu et al. 2014a; Hu et al. 2014b. The UCD_P model includes all the important processes for primary PM, but does not include secondary aerosol formation, coagulation, and nucleation. Sensitivity analyses indicate that these omitted processes have important contribution to total PM (primary+secondary), but generally have a less than 10% impact on annual average primary PM concentrations (Hu et al., 2014b). The WRF predicted wind field, one of the key meteorological parameters for determining the primary PM concentrations, is generally biased high on stagnant days, leading to underprediction of high primary pollution events. Uncertainties in emissions, such as lack of high temporal resolution of residential sources and incomplete chemical source profiles for 157 sources, also lower the model ability to reproduce some of the observed strong day-to-day variations. As a result, model predictions are in better agreement with measurements over longer averaging time (e.g., $\geq$ 1 month) than when day-to-day variations are considered. For instance, longer averaging time increased the overall correlation for $PM_{2.5}$ EC from 0.89 (1 day) to 0.94 (1 month), and overall increased the number of species with strong correlations (Hu et al., 2014b). The present study focused on exposure averaged on the entire pregnancy period and on specific pregnancy trimesters, which should minimize the impact of errors in the prediction of daily variations.

A complete validation study for the UCD_P predictions, including comparisons between predictions by source and the results of source apportionment studies conducted at five locations throughout California and during different episodes, has been conducted (Hu et al., 2014a). Excellent agreements were observed between source contributions modeled by UCD_P and estimated by chemical mass balance models, for mobile sources and wood burning.

The degree of agreement was also good for meat cooking, except in a specific rural setting (Angiola). This however might be due to high uncertainties in the measurement of cholesterol, that was used as an organic marker for meat cooking (Hu et al., 2014a). The agreement between modeled concentrations and the results of source apportionment studies across several locations and in different episodes builds our confidence in the model results at other locations and time.

In the analyses, we decided a priori to include only PM components for which correlations between monthly averaged predictions and measured values (both in $PM_{2.5}$, since measurement results for most components were available only for that fraction) were >0.6 in Los Angeles. Correlations were >0.8 for EC, potassium, chromium, iron, arsenic, manganese, copper, nickel and lead in $PM_{2.5}$ (Hu et al., 2014b). No validation results were available for primary OC because secondary formation accounts for a significant fraction of total OC mass. $PM_{0.1}$ mass prediction agreed well with available measurements across all Californian sites (that were available from the literature and had varying temporal resolution, from 3 days to 5 months, $R=0.92$). EC was the only $PM_{0.1}$ component for which the correlation between UCD_P prediction and measurements could be evaluated, and this was also found to be high ($R=0.94$, $N=8$ sites) (Hu et al., 2014a). There is greater uncertainty in the metal composition results for $PM_{0.1}$ than for $PM_{2.5}$, since insufficient $PM_{0.1}$ metal measurements were available for validation with robust statistical analysis. This is likely due to the difficulty in measuring minute quantities of elemental species in the $PM_{0.1}$ size fraction (Hu et al., 2014a). Predictions for metals in $PM_{0.1}$ might be correct but could not be rigorously evaluated so far and were thus left unconstrained.

Presently, our findings based on primary particles by source and composition can only be compared to a few other studies that were all based on measured $PM_{2.5}$ data. Bell et al. (2010, 2012) studied the associations between term LBW and $PM_{2.5}$ by source and composition averaged at the county resolution from monitoring station measurements in four Connecticut and Massachusetts counties. This research was later extended to the Northeastern and Mid-Atlantic regions of the US for $PM_{2.5}$ composition (Ebisu and Bell, 2012). In Los Angeles County, Wilhelm et al. (2012) conducted a similar study but assigned exposure based on 22-months of monitoring station data for women living within 8 km of the stations. In Atlanta, Darrow et al. (2011) assigned $PM_{2.5}$ element concentrations measured at one central site to subjects living within five surrounding counties. The European ESCAPE and LISA studies examined PM absorbance, a marker for elemental carbon (Pedersen et al., 2013; Slama et al., 2007). Despite exposure metrics of different natures in these studies, their results are qualitatively consistent with ours for $PM_{2.5}$ EC (Bell et al., 2010; Darrow et al., 2011; Ebisu and Bell, 2012; Pedersen et al., 2013; Slama et al., 2007; Wilhelm et al., 2012), potassium (Bell et al., 2012), iron (Bell et al., 2010), titanium (Bell et al., 2012; Ebisu and Bell, 2012) and nickel (Bell et al., 2010; Ebisu and Bell, 2012). No studies that examined $PM_{2.5}$ OC reported significant associations (Darrow et al., 2011; Ebisu and Bell, 2012; Wilhelm et al., 2012). However, these studies relied on measured data with a large portion of secondary OC, whereas UCD_P modeled only primary OC. In Atlanta, the summed mass of several water soluble metals in $PM_{2.5}$ (chromium, copper, iron, manganese, nickel and vanadium) was associated with a decrease in mean birth weight (Darrow et al., 2011). The same exposure metric (excluding vanadium, which contributes very little to mass) was associated with an increase in LBW risk in our study (data not shown). Some studies suggest possible influences of chromium (Junaid et al., 1996) on birth weight reduction in animals. In summary, our analyses identified a number of chemical species as potentially harmful. However, observed associations might be misleading if these species are strongly correlated with other pollutants that increase LBW risk, for instance if they share common sources, similar dispersion patterns and chemical properties. Therefore, these results call for confirmation in other study settings.

Analyses of PM by source revealed positive associations between LBW and PM from most evaluated sources. These findings are supported by other studies for meat cooking and gasoline (Wilhelm et al., 2012), diesel (Slama et al., 2007; Wilhelm et al., 2012), traffic related $PM_{2.5}$ overall (Bell et al., 2010) and wood burning (Boy et al., 2002). Fast food restaurants and road traffic are both important contributors to $PM_{0.1}$ emissions (Abernethy et al., 2013) and $PM_{0.1}$ might be the pollutant causing the association between these sources and LBW. However, primary $PM_{2.5}$ and $PM_{0.1}$ from meat cooking and from traffic are very strongly correlated (across sources and fractions), making it difficult to disentangle the influence of each source and each fraction. Most of particle emissions from meat cooking are due to commercial meat cooking in our study setting. Commercial meat cooking and traffic sources likely correlate in space, since commercial restaurants and fast-food stores may be more densely located in areas with a dense transportation network due to marketing reasons. Positive associations were also observed between LBW and $PM_{2.5}$ or $PM_{0.1}$ from high sulfur sources, which include a wide variety of sources (e.g., electricity generation, petroleum refining, aircraft). Conducting more thorough investigations by source subtype would be needed to get more insight into these observed associations.

The EBK approach we used to interpolate measured pollutants concentrations allowed retaining both their temporal and spatial variability. However, because of its high computational cost, temporal variability in air pollution measurement was not considered at a finer than monthly resolution. In order to estimate the impact of the resulting approximation in exposure calculation on odds ratio estimates, we compared results obtained using UCD_P daily estimates and monthly estimates. As expected, estimating exposure for the entire pregnancy period by using daily data (Table 2) yielded very similar results to those obtained when exposure data were previously averaged by calendar month (Appendix Table A.10). Differences in odds ratios were generally not visible after 3-digit rounding. Such differences were also slight when pregnancy trimesters were considered (Appendix Table A.11)

For the spatial resolution, EBK does not incorporate spatial covariates for prediction as would do land use regression or cokriging models. It therefore models the general trends in spatial variations. For this reason, we only applied EBK to pollutants that exhibit strong regional trends ($PM_{2.5}$, O_3 and NO_2). EBK-produced variance maps reflect the uncertainty in prediction estimates. However, weighting regressions by the inverse of this variance had no noticeable influence on ORs and only slightly reduced confidence intervals (data not shown). A previous study in Los Angeles County identified an association between LBW and total $PM_{2.5}$ during the third trimester only (Ghosh et al., 2012), whereas we observed significant associations for exposure during the entire pregnancy and each pregnancy trimester. This previous study however was restricted to subjects living within 8 km from monitoring stations (Ghosh et al., 2012). The EBK approach allowed including all Los Angeles County births, yielding greater statistical power.

The finer the spatial resolution of the exposure metrics considered (e.g., traffic density indices, road length and distance to roads), the more important the precision of subject geocoding. After restricting analyses to subjects with the best geocoding precision (exact parcel), associations remained significant for road length within a 50 m buffer and for living within 50 m of a major road (the OR even increased to 13% (95% CI: 4–22%) for "living within 50 m of a freeway or highway"). Traffic density was not

associated with LBW risk anymore for a 50 m buffer. Loss of statistical power due to reduced sample size might have contributed to this change. Our findings of increased LBW risk for living within 50 m of highways or freeways are supported by similar findings from Vancouver, Canada (Brauer et al., 2008). Other studies failed to detect such associations (Barnett et al., 2011). However, the rarity of this exposure situation makes it less likely for smaller cohorts to detect a slight association with LBW. The observed associations in close proximity to traffic sources are of particular interest since a recent study identified truck route length within 50 m of measurement sites as a major determinant of $PM_{0.1}$ number concentrations (Abernethy et al., 2013).

Our study has some limitations. The personal exposure of mothers during pregnancy could not be estimated in this large cohort since we had no time-activity information and pollution levels can vary substantial among micro-environments (e.g. workplace, public transportation) (Wu et al., 2011a). In addition, our air pollution metrics relied on maternal home address at the time of delivery because of a lack of data on residential history. All these sources of exposure measurement error contribute random error to the epidemiologic results, and might also potentially generate bias.

While socio-demographic data in birth certificates are thought to be accurate, more uncertainty surrounds the completeness of maternal diseases reporting, and of gestational age estimates that were mostly based on reported last menstrual period. Adjusting for maternal height, pre-pregnancy BMI and weight gain did not markedly modify ORs. Data on maternal smoking during pregnancy were also available for years 2007 and 2008, but these data were not used because of potentially serious under-reporting by comparison with other sources (California Department of Health Services, 2006). The lack of adequate data to adjust for maternal smoking is probably the major limitation of this study. In California, the prevalence of smoking during pregnancy was lowest in Hispanic women ($<6\%$) (California Department of Health Services, 2006), the subgroup in which we observed the highest ORs and that represents more than 60% of the study population. We adjusted for major determinants of maternal smoking associated with air pollution exposure – age, race/ethnicity and socioeconomic status (Murin et al., 2011). We can however not exclude a possible influence of smoking on our results.

Higher ORs were observed in infants of mothers with chronic hypertension and with diabetes (for ozone and traffic indexes only for the latter). These original findings are potentially of high public health interest. However because of potential under-reporting, it is uncertain to which extent women with reported diseases on birth certificates are representative of all women suffering from these diseases. Higher ORs for total $PM_{2.5}$ in women with higher BMI also constitute an original finding. Both obesity and exposure to air pollution are associated with systemic inflammation (Kannan et al., 2006; Rodriguez-Hernandez et al., 2013), that is a hypothesized pathway to LBW (Kannan et al., 2006). Inflammation is also a common feature of hypertension and diabetes (Rodriguez-Hernandez et al., 2013). Further research would be necessary to confirm effect modification of the relationships between air pollution and LBW by hypertension, diabetes and BMI, and if confirmed, to investigate inflammation as a possible mechanism for such interactions.

5. Conclusions

This study is the first to report a positive association between exposure to $PM_{0.1}$ and term LBW. Several chemical species in PM were also identified as potentially harmful, in broad agreement with recent research. Consistent results obtained using complementary exposure matrices support previous evidence that primary traffic-related pollutants might increase LBW risk. The suggested influence of other sources such as commercial meat cooking and wood burning constitutes emerging evidence that deserves further investigation. Several population subgroups with potentially higher susceptibility were identified – infants of mothers with a lower education, Hispanic ethnicity, diabetes, chronic hypertension and high BMI.

Background: Numerous studies have linked criteria air pollutants with adverse birth outcomes, but there is less information on the importance of specific emission sources, such as traffic, and air toxics.

Objectives: We used three exposure data sources to examine odds of term low birth weight (LBW) in Los Angeles, California, women when exposed to high levels of traffic-related air pollutants during pregnancy.

Methods: We identified term births during 1 June 2004 to 30 March 2006 to women residing within 5 miles of a South Coast Air Quality Management District (SCAQMD) Multiple Air Toxics Exposure Study (MATES III) monitoring station. Pregnancy period average exposures were estimated for air toxics, including polycyclic aromatic hydrocarbons (PAHs), source-specific particulate matter < 2.5 μm in aerodynamic diameter ($PM_{2.5}$) based on a chemical mass balance model, criteria air pollutants from government monitoring data, and land use regression (LUR) model estimates of nitric oxide (NO), nitrogen dioxide (NO_2) and nitrogen oxides (NO_x). Associations between these metrics and odds of term LBW (< 2,500 g) were examined using logistic regression.

Results: Odds of term LBW increased approximately 5% per interquartile range increase in entire pregnancy exposures to several correlated traffic pollutants: LUR measures of NO, NO_2, and NO_x, elemental carbon, and $PM_{2.5}$ from diesel and gasoline combustion and paved road dust (geological $PM_{2.5}$).

Conclusions: These analyses provide additional evidence of the potential impact of traffic-related air pollution on fetal growth. Particles from traffic sources should be a focus of future studies.

Key words: air pollution, air toxics, intrauterine growth retardation, low birth weight, traffic. *Environ Health Perspect* 120:132–138 (2012). http://dx.doi.org/10.1289/ehp.1103408 [Online 11 August 2011]

Air pollution has been linked to low birth weight (LBW) and preterm birth, yet there is no consensus on pollutants or sources responsible for these adverse outcomes. In our previous research in the Los Angeles (LA) Air Basin of Southern California, we observed most consistent associations for high levels of carbon monoxide (CO) and particulate matter with aerodynamic diameter < 10 μm (PM_{10}) during the third trimester and term LBW (Ritz and Yu 1999; Wilhelm and Ritz 2005). Our combined results for CO and PM_{10}, as well as our research associating residential proximity to traffic during pregnancy with odds of term LBW (Wilhelm and Ritz 2003), suggest that traffic exhaust pollutants may be causative agents of interest for fetal development.

Research in urban areas worldwide has also indicated associations between fetal growth restriction and atmospheric levels of CO, nitrogen dioxide (NO_2, another criteria pollutant indicative of traffic), and particulate matter (Shah and Balkhair 2011). However, two of four studies relying on residential traffic levels to estimate exhaust exposure (Brauer et al. 2008; Genereux et al. 2008; van den Hooven et al. 2009; Zeka et al. 2008) reported null associations. Several studies associated ambient and personal measures of polycyclic aromatic hydrocarbons (PAHs) with reduced fetal growth (Choi et al. 2008; Dejmek et al. 2000; Perera et al. 2003; Vassilev et al. 2001). PAHs are of interest because they are fuel combustion by-products and can be carried into the body by ultrafine particles < 0.1 μm in aerodynamic diameter (UFP), the main size component of particulate matter directly released by on-road vehicles (Sioutas et al. 2005). PAHs may disturb fetal development, possibly through adverse changes in placental transport or through oxidative stress pathways (Jedrychowski et al. 2010; Perera et al. 2004; Šrám et al. 1999).

Ambient air monitoring data are unlikely to capture the greater spatial heterogeneity of pollutants directly emitted from traffic (Zhou and Levy 2007; Zhu et al. 2002). Because personal measurements of UFP, PAHs, and other traffic constituents are too costly and logistically difficult in large, population-based studies, investigators have used modeling techniques to estimate traffic exposures more accurately than simpler roadway proximity measures. Land use regression (LUR) models based on neighborhood-scale pollutant measurements and geographic information systems (GIS) information on pollution sources and meteorology are examples (Jerrett et al. 2007). LUR models are usually based on pollutants more easily measured, for example, nitric oxide (NO), NO_2, and nitrogen oxides (NO_x), as proxies for the mix of toxics in traffic exhaust. To date, six epidemiologic studies, all outside of the United States, used LUR modeling techniques to examine traffic impacts on birth outcomes (Aguilera et al. 2009; Ballester et al. 2010; Brauer et al. 2008; Gehring et al. 2011a, 2011b; Slama et al. 2007); four reported positive associations for various measures of reduced fetal growth.

Here we used three different exposure data sources to examine odds of term LBW in Los Angeles, California, women when exposed to high levels of traffic-related air pollutants prenatally. We created pregnancy exposure estimates based on *a*) government monitoring data for criteria pollutants; *b*) LUR prediction surfaces for NO, NO_2, and NO_x we developed for the LA Basin (Su et al. 2009); and *c*) a unique resource of air toxics monitoring data collected during 2004–2006 by the South Coast Air Quality Management District (SCAQMD) as part of the Multiple Air Toxics Exposure Study (MATES III). These latter data include information on atmospheric levels of various traffic-related air toxics, as well as estimates of source contributions to particulate matter < 2.5 μm in aerodynamic diameter ($PM_{2.5}$) levels based on a chemical mass balance (CMB) analysis.

Materials and Methods

Study population. Electronic birth certificate records for all births occurring 1 June 2004 to 30 March 2006 to women residing in LA County, California, were assembled from the California Department of Public

Received 5 January 2011; accepted 11 August 2011.

Health (n = 276,891). We excluded infants with recorded defects (n = 14,777), missing gestational ages (n = 12,159), implausible gestational ages (< 140 days or > 320 days, n = 2,540), implausible birth weights (< 500 g or > 5,000 g, n = 371), and nonsingleton pregnancies (n = 5,629), leaving 241,415 total births and 220,528 (91.3%) term births (born at ≥ 37 completed weeks of gestation). Although MATES air toxics measurements began on 1 April 2004, we selected births starting 1 June 2004 to ensure available monitoring data covered at least part of pregnancy (i.e., last trimester).

For these 220,528 births, residential addresses at delivery reported on birth certificates were mapped using a custom geocoder (Goldberg et al. 2008) [see Supplemental Material, Table 1, for details (http://dx.doi.org/10.1289/ehp.1103408)]. The geocoded residential locations (n = 219,811; 99.7%) were then intersected with locations of seven MATES III monitoring stations in LA County (Supplemental Material, Figure 1), and women living within 5 miles were selected (n = 100,938; 45.9%). A 5-mile radius was used to balance the need for a large sample size with an effort to reduce exposure misclassification, assuming air pollution measurements best represent exposures for women living closer to stations. Among the 100,938 term births, 4.0% were geocoded at the ZIP code level and 0.03% (30 subjects) at the city/county subdivision level.

This research was approved by the University of California Los Angeles Office of the Human Research Protection Program and the California Committee for the Protection of Human Subjects.

Exposure assessment. **Monitoring station exposure measures.** For 10 of 33 air toxics measured by SCAQMD [see Supplemental Material, Table 2 (http://dx.doi.org/10.1289/ehp.1103408)], we extracted 24-hr averages collected every 3 days at MATES III monitoring stations located within 5 miles of each woman's residence. As part of MATES III, monthly composite $PM_{2.5}$ filter samples were speciated, and the U.S. Environmental Protection Agency CMB receptor model 8.2 was used to estimate diesel and other source contributions to $PM_{2.5}$ levels during the 2-year study period. In the CMB model, the ambient concentration of chemical species i is expressed as a linear equation:

$$C_i = \sum_{j=1}^{p} a_{ij} S_j, i = 1, n, \qquad [1]$$

where a_{ij} is the fractional concentration of chemical species i in source j, S_j is the total mass concentration contributed by source j, p is the number of sources, and n is the number of species, and a least-squares fitting approach is used to estimate C_i (SCAQMD 2008). Monthly average $PM_{2.5}$ concentrations (micrograms per cubic meter) from the following sources were quantified based on the CMB model: diesel exhaust, gasoline exhaust, ammonium nitrate, ammonium sulfate, biomass burning, cooking operations, sea salt, geological (paved road dust), and residual oil burning.

We averaged these data over the following pregnancy periods, relying on the date of birth and gestational age reported on the birth certificate: first trimester (estimated first day of last menstrual period through day 92), second trimester (days 93–185), third trimester (day 186 through birth), and the entire pregnancy. We implemented a 50% completeness criterion to ensure sufficient numbers of daily or monthly readings in each pregnancy averaging period [see Supplemental Material, Table 3, for details (http://dx.doi.org/10.1289/ehp.1103408)].

Data from all stations within 5 miles of a woman's residence that met the completeness criteria were used to generate exposure averages, with inverse-distance weighting of values when more than one station was available. If no stations met the completeness criteria, the value for the exposure period was set to missing.

We also generated criteria pollutant exposure averages, assigning women living near a MATES III station that measured only air toxics to other stations within 5 miles that measured criteria pollutants. Hourly measurements for CO, NO_2, NO, NO_x, and ozone (O_3) (1000–1800 hours) were first averaged over each day if sufficient data were available. These daily averages as well as 24-hr measurements for PM_{10} and $PM_{2.5}$ (collected every 6 and 3 days, respectively) were then averaged over pregnancy periods, again implementing the completeness criteria in Supplemental Material, Table 3 (http://dx.doi.org/10.1289/ehp.1103408). For subjects within 5 miles of more than one station, daily values were inverse distance weighted.

LUR exposure measures. We also extracted NO, NO_2, and NO_x concentration estimates at residential locations from LUR model surfaces we previously developed for the LA Basin (see Su et al. 2009). The LUR surfaces were based on 2-week average Ogawa NO_2 and NO_x measures we collected in September 2006 and February 2007 at 181 locations simultaneously throughout LA County. Final regression models explained 81%, 86%, and 85%, respectively, of the variance in measured NO, NO_2, and NO_x concentrations. Cross-validation analyses suggested high prediction accuracy in the range of 87–91%.

The LUR models most closely approximate annual average concentrations (Su et al. 2009). Thus, in addition to using these unseasonalized estimates, we also created seasonalized LUR measures using government monitoring station measurements nearest to home locations to incorporate yearly and monthly air pollution variations. For example, the LUR estimates for NO were adjusted (multiplied) by the ratio of average ambient NO during each pregnancy month to annual average ambient NO (2006–2007) to generate pregnancy month–specific values. These seasonalized monthly LUR values were then averaged over each pregnancy period. We applied the exclusion criteria described above when generating the pregnancy month scaling factors for NO, NO_2, and NO_x, and scaling factors for women within 5 miles of more than one station were based on inverse distance–weighted averages.

Statistical analyses. We calculated correlation coefficients and performed a factor analysis (using principal components analysis for initial factor extraction and varimax rotation) to examine clustering among the various air pollution exposure metrics. Associations between air pollution exposure and odds of term LBW (< 2,500 g) were examined using single- and multiple-variable logistic regression models. We calculated odds ratios (ORs) and 95% confidence intervals (CIs) for interquartile range (IQR) and specific unit increases in each exposure metric. We adjusted for maternal age, race/ethnicity, education, and parity (see Table 1 for categories), and gestational age (in weeks) and gestational age squared, as these variables were found to be important confounders in our previous analyses (Ritz and Yu 1999; Wilhelm and Ritz 2003, 2005). We also evaluated changes in OR estimates when additionally controlling for sex of the infant, prenatal care, payment source for prenatal care, whether the mother was born in the United States, maternal birthplace, and a previously developed socioeconomic status (SES) metric (Cheng et al. 2009; Yost et al. 2001). For the SES measure (standardized score for each census block group), principal component analysis was used to develop an index from seven U.S. Census 2000 variables. Because these additional factors did not change air pollution effect estimates by ≥ 5%, they were not included in final models.

Results

Characteristics of study populations. Women residing within 5 miles of MATES III monitoring stations were younger, more likely to be Hispanic, more likely to be born in Mexico, less educated, and much more likely to use Medi-Cal or other government programs versus private insurance for prenatal care compared with the entire population of mothers residing in LA County and

delivering infants during the same time period [see Supplemental Material, Table 4 (http://dx.doi.org/10.1289/ehp.1103408)].

The prevalence of term LBW in the study population was 2.1%. In univariate models, odds of term LBW were greater for female infants, firstborn infants, and infants born to younger mothers (< 25 years of age), mothers receiving no prenatal care or receiving care after the first trimester, and to mothers using Medi-Cal or other governmental programs for prenatal care payment (Table 1). Odds of term LBW were lower for infants born to non-Hispanic white mothers and to mothers with more than a high school education (> 12 years). Infants of mothers born in the United States had increased odds of term LBW compared with infants of foreign-born mothers, mostly because of lower odds of term LBW for infants of mothers born in Mexico.

Table 1. Demographic characteristics by outcome group and crude ORs (95% CI) for term LBW.[a]

Parameter	Term LBW cases (*N* = 2,321) *n* (%) or mean ± SD	Noncases (*N* = 98,617) *n* (%) or mean ± SD	Crude term LBW OR (95% CI)

[a]Includes 100,938 term births during 1 June 2004 to 30 March 2006 to women residing within 5 miles of a MATES air toxics monitoring station. [b]"Other" race category includes Native American/American Indian, Indian, Filipino, Hawaiian, Guamanian, Samoan, Eskimo, Aleut, Pacific Islander, Other (specified). In regression models, nonwhite Hispanics were included in both the Hispanic category and their specified race category (99.3% of Hispanics stated their race as white).

Exposure metric distributions and correlations. **Entire pregnancy averages.** We provide information on distributions of entire pregnancy averages in Table 2 and correlations in Supplemental Material, Table 5 (http://dx.doi.org/10.1289/ehp.1103408). In the factor analysis (Supplemental Material, Table 6), monitoring data–based entire pregnancy averages for the following pollutants clustered most strongly (factor 1): NO, NO_2, and NO_x, $PM_{2.5}$, elemental carbon (EC), organic carbon (OC), diesel $PM_{2.5}$, total PAHs (the largest constituent by mass being naphthalene), benzene, biomass burning $PM_{2.5}$, meat cooking $PM_{2.5}$, and ammonium nitrate. A second factor (factor II) represented several pollutants with higher concentrations in the coastal areas (SCAQMD 2008): vanadium, residual oil $PM_{2.5}$, and sea salt $PM_{2.5}$. Vanadium and residual oil $PM_{2.5}$ were strongly positively correlated, as vanadium (along with nickel) was used to identify the residual oil combustion source in the CMB analysis. Other pollutants that clustered positively within this coastal pollutant group were benzo[*a*]pyrene (BaP) and gasoline $PM_{2.5}$, whereas ozone loaded negatively on this factor. Ammonium sulfate loaded positively on factor II, but also on a third factor (factor III), suggesting coastal versus noncoastal spatial patterns were not as strong as for sea salt $PM_{2.5}$, residual oil $PM_{2.5}$, and vanadium. PM_{10} loaded positively on factors I and III, suggesting it does not reflect traffic toxics as strongly as the other pollutants in factor I. Benzo[*g,h,i*]perylene and CO averages loaded similarly on factors I and II, indicating less coastal versus noncoastal differences for these pollutants. All LUR metrics loaded separately on a fourth factor, reflecting their low overall correlation with the monitoring-based exposure metrics (Supplemental Material, Table 5). Finally, geological $PM_{2.5}$ (modeled based on paved road dust samples using iron, calcium, and silica as fitting species) was best represented as a separate fifth factor. Interestingly, gasoline and diesel $PM_{2.5}$ were not strongly correlated spatially in this data set and loaded on separate factors.

Trimester averages. Ambient measures of NO, NO_x, and total PAHs exhibited strong seasonal variability with peaks in winter, whereas O_3 and ammonium sulfate followed the opposite pattern with summer peaks. As a result, first- and third-trimester exposures for these pollutants were strongly negatively correlated (r = –0.8 to –0.9) (results not shown). Other pollutants with winter peaks but more moderate negative correlations between first- and third-trimester averages (r = –0.5 to –0.7) included seasonalized LUR estimates of NO and NO_x, benzene, EC and OC, and $PM_{2.5}$

from biomass burning, cooking, diesel, and gasoline sources. All other pollutants were less seasonally variable, especially vanadium and residual oil $PM_{2.5}$ (all trimester averages were positively correlated, with r = 0.4 to 0.9 and r = 0.6 to 0.9, respectively). Second-trimester and entire pregnancy averages for all pollutants were moderately to strongly correlated (r = 0.6 to 0.9).

Associations between exposure metrics and term LBW. We estimated an approximately 5% increase in adjusted odds of term LBW per IQR increase in entire pregnancy exposures to the following traffic exhaust markers: LUR estimates of NO, NO_2, and NO_x (unseasonalized and seasonalized), EC, and $PM_{2.5}$ from diesel and gasoline combustion (Table 3) [see Supplemental Material, Table 7, for effect estimates based on unit increases (http://dx.doi.org/10.1289/ehp.1103408)]. IQR increases in entire pregnancy exposure to geological $PM_{2.5}$ (representing paved road dust) were also associated with a 5% increase in odds of term LBW. Excluding births that were not geocoded at the parcel, lot, or street level (4.0%) from analyses changed OR estimates by ≤ 0.01. We did not observe associations with IQR increases in entire pregnancy exposures to any of the other pollutants we evaluated (Supplemental Material, Table 7).

For seasonalized LUR estimates of NO, NO_2, and NO_x and ambient measures of CO and $PM_{2.5}$, effect estimates for the first trimester were 1–6% greater than those for the third trimester in models including exposure measures for each trimester (results not shown). For EC and diesel, gasoline and geological $PM_{2.5}$, point estimates were similar, in general, across pregnancy trimesters. However, 95% CIs overlapped widely for all these measures. Overall, the moderate-to-strong negative correlations between first- and third-trimester exposure averages for many pollutants and strong positive correlations between second trimester and entire pregnancy exposure estimates for almost all pollutants limited our ability to identify pregnancy periods exhibiting greater susceptibility.

Discussion

We estimated an approximately 5% increase in the odds of term LBW per IQR increase in entire pregnancy averages of NO, NO_2, and NO_x as estimated by LUR, EC, and $PM_{2.5}$ from diesel and gasoline exhaust and paved road dust (geological $PM_{2.5}$). The LUR model was built on neighborhood-level measures of NO_x and captures small-scale variability in pollutant levels due to proximity to roadway emission sources. The diesel and gasoline exhaust $PM_{2.5}$ averages are direct markers of traffic sources. Although the geological source profile used in the CMB model was based on paved road dust, the association with this $PM_{2.5}$ source further underscores the importance of traffic (i.e., roadways indicator). Finally, EC is often considered a marker of diesel exhaust particles, although there are additional sources of this pollutant in the LA Basin. Altogether, our results for various traffic markers lend strong support to the hypothesis that traffic negatively affects birth weight.

Although diesel $PM_{2.5}$ and EC averages were correlated with total PAH averages (r ~ 0.7 to 0.8), we did not observe positive associations between entire pregnancy averages of PAHs and term LBW [Supplemental Material, Table 7 (http://dx.doi.org/10.1289/ehp.1103408)]. These findings might be attributable to the small number of subjects with entire pregnancy PAH averages available and/or the lack of information on spatial variation for these pollutants in our data set, because PAHs were only measured at two stations (West Long Beach and Downtown LA). A larger data set for LA with more

Table 2. Pollutant distributions for entire pregnancy averages.

information on PAH spatial distributions is required to examine associations further.

Bell et al. (2010) examined associations between birth weight and $PM_{2.5}$ constituents for women residing in Connecticut and Massachusetts and delivering during August 2000 through February 2004. Despite differences in study populations, study design, and constituents used in source apportionment, similarities with our results are notable. In the Northeast, entire pregnancy exposures to constituents most closely associated with motor vehicles, EC and zinc, were associated with lower birth weights and higher risk of term LBW, as were oil combustion–associated elements, vanadium and nickel, and road dust and related constituents such as silicon and aluminum (Bell et al. 2010). In LA County, we also observed positive associations between odds of term LBW and entire pregnancy exposures to EC, as well as diesel, gasoline, and geological $PM_{2.5}$ (paved road dust).

Despite low correlations between LUR and monitoring-based entire pregnancy exposure estimates, we observed positive associations between both metrics and term LBW. This finding suggests spatially heterogeneous local traffic pollution—presumably better represented by our LUR model—as well as regional traffic pollution—represented by the monitoring data—both contribute to increased odds of term LBW. However, both types of metrics may be imperfect markers of the causal pollutants of interest. The LUR models were built on neighborhood-level NO_2 and NO_x concentrations because of the relative ease of measurement. LUR-estimated NO, NO_2, and NO_x have been associated with other health outcomes (Brauer 2010) and are typically considered markers of the suite of pollutants in vehicle exhaust. However, there is limited information on how well spatial and temporal patterns of these pollutants reflect similar patterns for specific toxics of health interest such as PAHs and UFP. Beckerman et al. (2008) reported strong correlations between 1-week average concentrations of NO, NO_2, and NO_x collected by passive monitors at varying distances from a major expressway in Toronto, Canada, and short-term (10-min) measures of UFP (r = 0.8 to 0.9). Neighborhood-level monitoring of PAHs, UFP, and other air toxics in conjunction with passive NO, NO_2, and NO_x monitoring in LA is needed to determine whether correlations are similar to those reported for Toronto. In addition, temporal adjustment of LUR pollution surfaces using ambient monitoring station data may not be appropriate because of the unvalidated assumption that ambient monitoring site measures and LUR modeled concentrations co-vary over space. Fewer cases (n = 577) had seasonalized versus unseasonalized LUR exposure metrics available, because we relied on ambient monitoring data for temporal adjustment [see Supplemental Material, Table 3, for a description of exclusion criteria for monitoring data (http://dx.doi.org/10.1289/ehp.1103408)]. The unseasonalized LUR measures also best represent spatial, long-term (annual average) exposure contrasts versus pregnancy period–specific exposures. Nonetheless, we observed associations between both unseasonalized and seasonalized LUR measures, suggesting that either local, high-traffic exposures throughout the entire pregnancy are important for term LBW or that our crude seasonalization may not have captured temporal variations in local exposures adequately enough to detect differences across pregnancy periods if they are important.

There is limited animal evidence regarding air pollutants of interest for adverse fetal development. Higher exposure to PAHs during pregnancy measured via personal monitoring, PAH–DNA adducts in umbilical cord blood, and government monitoring stations has been linked to decreased birth weight, length, and head circumference and to small size for gestational age in epidemiologic studies (Choi et al. 2008; Dejmek et al. 2000; Perera et al. 2003, 2004; Vassilev et al. 2001). PAHs may directly affect early trophoblast proliferation, causing suboptimal placentation, reduction in oxygen and nutrient exchange with the fetus, and impairment of fetal growth (Dejmek et al. 2000; Veras et al. 2008).

Oxidative stress may be another biological pathway of interest. UFP in LA have been shown to induce oxidant stress responses and inflammation in experimental studies; these effects may be attributable to the action of PAHs, metals, and related compounds that lead to the production of cytotoxic reactive oxygen species (Cho et al. 2005; Li et al. 2003; Nel et al. 2001; Zhang et al. 1995). Animal and human evidence suggests oxidative stress leads to poor fetal growth (Jedrychowski et al. 2010).

One limitation of this study was the relatively short period (22 months) for which air toxics and speciated $PM_{2.5}$ monitoring data were available, leading to moderate-to-strong negative correlations between first and third trimester measures for many pollutants and strong positive correlations between second trimester and entire pregnancy averages for almost all pollutants. These correlations limited our ability to identify pregnancy periods with greater susceptibility. However, for EC and diesel, gasoline and geological $PM_{2.5}$, we did not detect differences in effect estimates across pregnancy in multitrimester models (results not shown).

We did not observe associations between entire pregnancy averages of CO and $PM_{2.5}$ and odds of term LBW, possibly because of inadequate spatial information for these pollutants (only four of seven MATES III monitors measured criteria pollutants, and for the other monitors we relied on more distant criteria pollutant stations located within 5 miles). In previous studies, we included 4–6 years of births and 12–18 air monitoring stations and thus were able to restrict analyses to women residing within 2 miles of a station (Ritz and Yu 1999; Wilhelm and Ritz 2005). Here we included women residing within 5 miles of a monitoring station to achieve a sufficient sample size, and extrapolating over longer distances likely increased exposure misclassification.

We used the SCAQMD's MATES III study results to estimate pregnancy exposures to source-specific $PM_{2.5}$ concentrations. SCAQMD (2008) provides a discussion of their data collection and source apportionment modeling methods. Because $PM_{2.5}$ samples were composited for speciation analyses, only monthly average source-specific $PM_{2.5}$ values were available to derive pregnancy averages; thus, temporal variation may not be well represented. The following CMB optimal performance criteria were used by SCAQMD to assess model fit: R^2 values of 0.8–1.0; chi-square values of < 4.0; and differences between calculated and measured $PM_{2.5}$ mass of < 20%. SCAQMD conducted sensitivity tests using various source profiles for diesel and gasoline exhaust, biomass burning, and meat cooking. Final source profiles were selected based on the above performance criteria and comparison of results with previous measurement studies in the LA Basin. For example, the SCAQMD used two separate gasoline source profiles in the CMB model: one developed for the LA Basin as part of the Department of Energy's Gasoline/Diesel Split Study (Fujita et al. 2006) and a second developed as part of the Northern Front Range Air Quality Study (NFRAQS) (Zielinska et al. 1998). Although there were only minor impacts on other source category estimates, the proportion of $PM_{2.5}$ attributed to gasoline combustion differed substantially depending on which profile was used. Here we used results based on the NFRAQS profile, as recommended in SCAQMD (2008), but acknowledge this as a source of uncertainty in our results for $PM_{2.5}$ attributed to gasoline motor vehicles.

Another source of exposure measurement error is the reliance on address information reported on birth certificates, which does not account for residential mobility during pregnancy. Previous studies indicate that 12–28% of women change residence during pregnancy (Chen et al. 2010; Lupo et al. 2010; Madsen et al. 2010). In our previous population-based survey of women residing in 111 ZIP codes

in LA County and delivering in 2003, 22% of women reported moving during pregnancy (Ritz et al. 2007). Air pollution effect estimates based on ambient monitoring data remained unchanged or were slightly strengthened when we restricted analyses to women who did not move. However, smaller spatial-scale exposure estimates (e.g., LUR) may be subject to more error due to residential mobility than regional, background exposure estimates based on monitoring station data.

For this study we relied on information recorded on California birth certificates, limiting our ability to control for certain confounders, such as maternal active or passive smoking. In a previous study incorporating survey data (Ritz et al. 2007), air pollution effect estimates for preterm birth did not change appreciably when we added smoking variables to models already including maternal age, education, race/ethnicity, and parity. Additionally, our population was predominately Hispanic and foreign-born, and prenatal smoking rates among these groups are generally low (< 3%) (California Department of Public Health 2006). Confounding by other SES-related factors potentially correlated with air pollution is also of concern. Our air pollution effect estimates did not change appreciably when we adjusted for prenatal care initiation or payment source or for a census-based SES measure. Also, in our survey-based study, adjustment for family income did not change air pollution effect estimates for preterm birth after adjustment for birth certificate variables (Ritz et al. 2007).

A major strength of our study was the use of novel air toxics and LUR exposure information in addition to routine government monitoring station data for criteria pollutants to help identify specific emission sources of concern for fetal health. Odds of term LBW were positively associated with LUR exposure metrics and $PM_{2.5}$ from diesel and gasoline combustion and paved road dust, suggesting potential importance of mobile source emissions specifically for this outcome. Entire pregnancy averages for CO and $PM_{2.5}$ were correlated with PAH averages, suggesting that these pollutants could have acted as markers for PAHs in previous studies, at least in the LA basin. Ideally, future birth outcome studies would use larger data sets, with neighborhood-level monitoring of PAHs and possibly speciated $PM_{2.5}$ measured in each season.

Conclusions

These analyses provide additional evidence that local as well as regional traffic-related air pollution adversely impacts fetal growth in Southern California. The positive associations we observed for traffic source particles support previous studies and call for additional research focused on these pollutants. Future birth outcome studies would benefit from measurement and GIS-based models of particle and PAH exposures.

Correction

A coding error necessitated changes in some of the values in the tables originally published online. These have been corrected here, and do not change the major results or conclusions of the study.

Abstract

Importance: Polycyclic aromatic hydrocarbons are widespread urban air pollutants from combustion of fossil fuel and other organic material shown previously to be neurotoxic.

Objective: In a prospective cohort study, we evaluated the relationship between Attention Deficit Hyperactivity Disorder behavior problems and prenatal polycyclic aromatic hydrocarbon exposure, adjusting for postnatal exposure.

Materials and Methods: Children of nonsmoking African-American and Dominican women in New York City were followed from *in utero* to 9 years. Prenatal polycyclic aromatic hydrocarbon exposure was estimated by levels of polycyclic aromatic hydrocarbon- DNA adducts in maternal and cord blood collected at delivery. Postnatal exposure was estimated by the concentration of urinary polycyclic aromatic hydrocarbon metabolites at ages 3 or 5. Attention Deficit Hyperactivity Disorder behavior problems were assessed using the Child Behavior Checklist and the Conners Parent Rating Scale- Revised.

Results: High prenatal adduct exposure, measured by elevated maternal adducts was significantly associated with all Conners Parent Rating Scale-Revised subscales when the raw scores were analyzed continuously (N = 233). After dichotomizing at the threshold for moderately to markedly atypical symptoms, high maternal adducts were significantly associated with the Conners Parent Rating Scale-Revised DSM-IV Inattentive (OR = 5.06, 95% CI [1.43, 17.93]) and DSM-IV Total (OR = 3.37, 95% CI [1.10, 10.34]) subscales. High maternal adducts were positivity associated with the DSM-oriented Attention Deficit/Hyperactivity Problems scale on the Child Behavior Checklist, albeit not significant. In the smaller sample with cord adducts, the associations between outcomes and high cord adduct exposure were not statistically significant (N = 162).

Conclusion: The results suggest that exposure to polycyclic aromatic hydrocarbons encountered in New York City air may play a role in childhood Attention Deficit Hyperactivity Disorder behavior problems.

Introduction

Polycyclic aromatic hydrocarbons (PAH), such as benzo[a]pyrene (B[a]P), are toxic air pollutants released during incomplete combustion of fossil fuel, tobacco, and other organic material [1]. They are also found in the diet. In New York City (NYC) and other urban areas, traffic and residential heating are major local sources. There is also some contribution from coal-burning sources in states upwind. Urban, minority populations in the U.S. often have disproportionate exposure to air pollution and are at greater risk for adverse health and developmental outcomes from this exposure [2–5]. All of the mothers in the Columbia Center for Children's Environmental Health (CCCEH) NYC cohort had detectable levels of PAH in prenatal personal air samples; 42% had detectable levels of B[a]P-DNA adducts in maternal blood; and 46% had detectable levels of B[a]P-DNA adducts in cord blood. B[a]P is considered a representative PAH and is highly correlated with other PAH class members [6]. PAH-DNA adducts reflect individual exposure to PAH, integrating exposure over a 2–3 month period [7]and via different routes (primarily inhalation and ingestion). Adducts provide a biologic dosimeter as they not only reflect inter-individual differences in exposure and uptake of PAH but also in detoxification and DNA repair [8,9].

Because of the heightened susceptibility of the fetus and young child, exposures to PAH and other environmental pollutants during the prenatal and early postnatal stages are of particular concern [10–13]. During the fetal period and early childhood years, the brain is rapidly developing and vulnerable to neurotoxic insults that may manifest as adverse outcomes in childhood and adulthood [14,15]. Laboratory studies of PAH exposure during the prenatal, neonatal, or adult periods have reported a range of neurodevelopmental and behavioral effects, [16,17] including hyperactivity [18,19]. In the present CCCEH cohort, prenatal exposure to PAH measured by prenatal air monitoring or B[a]P-DNA adducts in maternal or umbilical cord blood at delivery was associated with developmental delay at age 3 [20], reduced IQ at age 5 [21], and symptoms of anxiety/depression and attention problems at ages 6–7 [6].

Attention-deficit/hyperactivity disorder (ADHD) is the most common behavioral disorder diagnosed in children [22] and is often accompanied by anxiety and depression [23–26]. In our cohort, ADHD behavior problems and anxiety/depression at age 9 were significantly correlated ($r = 0.43$, $p<0.0001$). Children with ADHD are at increased risk of substance abuse, conduct, and mood disorders [27–30]. Family history, certain environmental contaminants, alcohol use, maternal smoking during pregnancy, pregnancy and delivery complications, and psychosocial adversity have been implicated or identified as risk factors for ADHD [31,32].

Prior data on air pollution and ADHD are suggestive. For example, a cross-sectional study found an association between ambient particulate matter (PM_{10}) and childhood ADHD [33]. In a longitudinal study, estimated exposure during infancy to elemental black carbon, based on air sampling data and land use regression modeling, was significantly associated with ADHD-related symptoms [34]. Another cohort study reported an association between attention and children's lifetime exposure to black carbon based on children's residence and a spatiotemporal model [35]. Ours is the first report of associations between individual measures of early-life exposure to PAH pollutants and ADHD behavior problems in children.

Methods

Sample selection

A complete description of the NYC cohort appears elsewhere [20,36]. Briefly, African-American and Dominican women who resided in Washington Heights, Harlem, or the South Bronx in NYC, U.S., were recruited between 1998 and 2006 through local prenatal care clinics. Enrollment was restricted to women who were non-active cigarette smokers; ages 18–35; non-users of other tobacco products or illicit drugs; free of diabetes, hypertension, or known HIV; and who had initiated prenatal care by the 20th week of pregnancy. The Institutional Review Board of the Columbia University Medical Center approved the study. Mothers signed a consent form, approved by the IRB, for themselves and their children at the time of enrollment and at every subsequent visit. The children sign an IRB-approved assent form beginning at age 7. The consent and assent forms are available in English and Spanish and clearly explain the study goals and procedures.

The sample included in the present analysis is composed of the children who had available data on at least one adduct measure (maternal or newborn), the CPRS and the CBCL assessments, and all covariates of interest ($N = 250$).

Maternal/child characteristics and home caretaking environment

Demographic, health and environmental conditions. A 45-minute structured questionnaire was administered by a trained bilingual interviewer during the last trimester of pregnancy to obtain demographic information, residential history, and health and environmental data such as active smoking (to confirm non-active smoking status) and passive smoking [36]. The questionnaire also elicited information on dietary PAH (consumption of broiled, fried, grilled or smoked meat), and socioeconomic information related to income and education. Postnatal interviews were administered in person at 6 months and annually thereafter to determine changes in residence, exposure to environmental tobacco smoke (ETS), and health and environmental conditions.

Maternal demoralization. Maternal demoralization, a measure of maternal nonspecific psychological distress that has been linked to neurodevelopment [37–39], was measured at each visit by the Psychiatric Epidemiologic Research Instrument Demoralization Scale (PERI-D) [40].

Non-verbal intelligence. The Test of Non-Verbal Intelligence-Second Edition (C-TONI-2) [41] was administered to the mothers when the child was about 3 years old.

Home assessment. Caldwell and Bradley's Home Observation for Measurement of the Environment (HOME) [42] was administered in the home by research workers, also when the child was about 3 years old, to assess physical and interactive characteristics of the child rearing environment.

Maternal ADHD. At the child's 7 year visit, mothers completed the Conners Adult ADHD Rating Scales (CAARS) [43]. Given the high heritability rate of ADHD [44], maternal ADHD symptoms on the CAARS were included as a covariate in our analyses.

Child anxiety/depression. Childhood ADHD and anxiety/depression are frequently comorbid conditions [24]. The continuous score for symptoms of anxiety/depression on the CBCL at age 9 [45] was included as a covariate.

Independent variables

Prenatal exposure: PAH-DNA adducts. Following delivery, maternal blood and umbilical cord blood samples were collected. Within several hours following collection, samples were

transported to the CCCEH Molecular Epidemiology Laboratory, processed, and stored at −70°C. B[a]P–DNA adducts in extracted white blood cell DNA were analyzed using the high performance liquid chromatography (HPLC)/fluorescence method which detects B[a]P tetraols [12,46]. Not all participants had adequate DNA quantity for adduct analysis.

Postnatal exposure: urinary PAH metabolites. At the CDC, a suite of PAH metabolites was measured in spot urine (collected from the child at ages 3 and 5) using automated liquid-liquid extraction and gas chromatography/isotope dilution high-resolution mass spectrometry [47–49]. Although PAH urinary metabolite have a short lifetime (half-life of 6–35 hours) [50], in conditions of chronic exposure they provide a useful measure of exposure to PAH [47,48]. Specific gravity (SG) measurements were used to control for urinary dilution of the samples using the following formula: freshweight metabolites for the subject*(mean SG-1)/(SG for that subject-1) [51,52].

Behavioral outcomes

ADHD behavior problems were assessed using two complementary parent-report instruments: the CBCL for ages 6–18 (CBCL) [53] and the CPRS- Revised: Long Version [54]. The CBCL is a screening instrument assessing childhood competencies, adaptive functioning, and problems [45]. The CPRS is a focused assessment of childhood ADHD and its common comorbid disorders [54,55]. Both are widely used instruments that measure ADHD problems and attention function and have been used to study their associations with diverse environmental contaminants [56–59]. Both instruments yield scales derived from the DSM-IV [60] that are intended to screen for ADHD-behavior problems and indicate those children requiring follow-up. Mothers self-administered the 80-item CPRS [54] and the 118-item CBCL [53] when their children were 9 years old, under the guidance of trained research workers. Outcomes analyzed included the CBCL DSM-oriented Attention Deficit/Hyperactivity Problems scale, and the CPRS ADHD Index and DSM-IV subscales (denoted as "Total", "Inattentive", and "Hyperactive-Impulsive"). The "Total" DSM-IV measure comprises the "Inattentive" and "Hyperactive-Impulsive" subscales. For both instruments, the child's responses were scored and summed to a raw score. T-scores were derived from raw scores based on the normative comparison sample as described in the administration manual and used to determine the child's classification [53,54]. On the CBCL DSM-oriented Attention Deficit/Hyperactivity Problems score, children above the 93rd percentile were classified as "borderline clinical", and those below the 93rd percentile were classified in the normal range [53]. The CPRS DSM-IV subscales and ADHD Index scores were dichotomized based on the classification of a T score >65 as "moderately to markedly atypical" and a T score ≤65 as "in the normal range" [54].

Statistical Analysis

As in prior analyses [6], adduct levels were dichotomized as detectable/non-detectable ("high/low"), with detectable levels observed in 42% of maternal and 46% of cord blood samples in the whole cohort. Dichotomization of exposure variables is less vulnerable to measurement error and permits comparison of the most highly exposed children to children with lower exposure. In our analyses, (1-hydroxynaphthalene, 2-hydroxynaphthalene, 2-hydroxyfluorene, 3-hydroxyfluorene, 9-hydroxyfluorene, 1-hydroxyphenanthrene, 2-hydroxyphenanthrene, 3-hydroxyphenanthrene, 4-hydroxyphenanthrene) were summed to provide a composite measure denoted "PAH metabolites". PAH metabolites in child urine at ages 3 or 5 were dichotomized at the respective medians for the entire cohort and treated as "high/low". In terms of data analysis, the age 5 metabolite level was preferentially selected, but if that measure was missing, the age 3 metabolite level was used. In secondary analyses, adducts and PAH metabolites were also treated as a continuous variable after log transformation.

Covariates were selected based on whether they were significant contributors to the model (at $p \leq 0.1$) for at least one of the outcomes and included: prenatal ETS exposure, child's sex, child's ethnicity, child's gestational age, mother's intelligence, mother's completed years of education prior to birth of the child, maternal prenatal demoralization, maternal ADHD symptoms, child's exact age at assessment (in months), the quality of the early home caretaking environment, and season at time of monitoring (heating vs. non-heating) (Table 1). We further adjusted for child anxiety/depression at age 9 since it is a well-documented comorbid condition with ADHD and symptoms overlap [24]. Moreover, we have previously found associations of PAH with child anxiety/depressive symptoms [6]. Dietary PAH, measured prenatally during the third trimester, was not a predictor of outcomes at $p \leq 0.1$. The associations between the dichotomized PAH exposure variables and continuous raw scores and dichotomized T scores for ADHD-related behavior were analyzed by Poisson and logistic regression, respectively.

Results

Maternal and cord adducts were not significantly correlated with prenatally air monitored PAH, ETS, or dietary PAH.

Table 1 presents the socio-demographic, outcome, and exposure characteristics of the children who had available data on maternal or cord adducts, stratifying on whether or not they had data on neurobehavioral outcomes and covariates of interest and were thus included (N = 250) or not included (N = 364) in the analysis. The two groups were similar except that the group included had a higher proportion of females and were younger at the CPRS assessment, though all assessments were given at approximately age 9. The level of adducts and percentage characterized as high vs. low did not differ between those included and not included. Comparing the group included (N = 250) with those children who did not have maternal or cord adduct data (N = 111), there were differences in terms of exact age at assessment for the CBCL and CPRS, home inventory scores, and percentage of mothers that had completed high school (data not shown).

Table 2 summarizes the distribution of CBCL and CPRS scores in the entire sample. Table 3 shows the number of children in the borderline or clinical range on the CBCL, and the number in the moderately to markedly atypical range on the CPRS. Consistent with other studies, there was substantial overlap between the number of children categorized in the moderately to markedly atypical range on the Hyperactive-Impulsive and Inattentive problems, as shown in Figure 1.

Table 4 summarizes the associations between maternal (N = 233) and cord adduct (N = 162) exposure and CBCL DSM-oriented Attention Deficit/Hyperactivity problems and all CPRS outcomes, adjusting for postnatal PAH exposure and selected covariates. When considering outcomes analyzed as continuous raw scores, all CPRS subscales were positively and significantly associated with high maternal adduct exposure. After dichotomizing the outcome measures, those with high maternal adducts had odds of being categorized as moderately to markedly atypical on the DSM-IV Inattentive and DSM-IV Total scales 5.06 (95% CI [1.43, 17.93]) and 3.37 (95% CI [1.10, 10.34]) times greater than those with low maternal adducts. High maternal adduct exposure

was also significantly and positively associated with the CDCL DSM-oriented Attention Deficit/Hyperactivity Problems scale, though results did not reach statistical significance.

In separate models with log transformed adduct and metabolite values as the exposure variables, the direction and significance of the associations between adducts and outcomes were the same as the models with the dichotomized exposure with the exception of the CBCL DSM-oriented attention deficit hyperactivity scale raw score and CPRS DSM-IV Total scale raw score, which became borderline significant ($p = 0.06$, and $p = 0.08$, respectively) (data not shown).

Parallel analyses in the smaller number of subjects with available cord adduct data (N = 162) exposure found non-significant or borderline significant associations with all outcomes (Table 4).

Discussion

The present results suggest that high prenatal exposure, taking into account the potential effects of postnatal PAH exposure, may

increase the risk of ADHD behavior problems. ADHD is a disorder that is known to impact school performance, social relationships, and occupational performance [61–66]. In the U.S. the annual societal cost of illness for ADHD is estimated to be between $36 and $52 billion, and the annual cost per individual is estimated to be $12,005 to $17,458 (2005) [67,68].

To our knowledge, there have been no prior epidemiological studies on the role of pre- and post-natal PAH exposure, here measured by chemical-specific biomarkers, on ADHD in school-age children. Prior experimental research and limited epidemiological studies have suggested links between PM and air pollution (elemental carbon and black carbon) and ADHD symptoms [33–35]. In the present longitudinal study high maternal adduct levels were not significantly associated with Attention Deficit/Hyperactivity problems on the CBCL screening test, but on the more detailed CPRS, consistently significant associations with a number of ADHD-related outcomes were seen. In particular, significant associations between high maternal adducts and the DSM-IV Total and DSM-IV Inattentive scales were observed in models treating CPRS scores as continuous and dichotomous outcomes. Consistency in the results across both of these outcome measures strengthens the conclusion that inattention is associated with prenatal PAH exposure.

The maternal and cord adducts were significantly but only modestly correlated ($r = 0.28$, $p < 0.0001$), probably because of the immaturity of the metabolic/detoxification and DNA repair systems in the fetus compared to the adult [69] and the differing genetic profiles of the mother and the child. The stronger relationship between the maternal adducts and ADHD-related outcomes than between the cord adducts and the same outcomes could be attributable to the effects of exposure on placental function and/or the fact that high levels of maternal adducts indicate that the mother has been highly exposed and is an efficient activator of PAH, resulting in higher transplacental exposure to reactive PAH intermediates. We used urinary PAH metabolites to assess postnatal exposure. This biomarker has been employed in many studies as an indicator of PAH exposure in the general population [70]. Although they represent recent exposure [71], the metabolites can provide a chronic measure of ambient PAH in populations with constant exposure [72].

The mechanisms by which PAH exposure might affect the developing brain are not fully understood. Several pathways have been suggested including endocrine disruption [73–75], binding to receptors for placental growth factors resulting in decreased exchange of oxygen and nutrients [76], binding to the human Ah receptor to induce P450 enzymes [77], DNA damage resulting in activation of apoptotic pathways [78–80], oxidative stress due to inhibition of the brain antioxidant scavenging system [81], and epigenetic alterations [82]. The prenatal period is critical because of the extensive structural and cellular-level changes that occur during this stage of development. However, because brain development and growth occurs throughout childhood, postnatal exposures to environmental pollutants may also affect children's neurodevelopment and behavior [83].

The strengths of the study include our ability to account for a number of potential confounding variables and to draw upon

Table 3. Number of children scoring in the borderline or clinical range on the CBCL and in the moderately to markedly atypical range on the CPRS in the analyses with maternal adducts or cord adducts[a].

individual pre- and post-natal exposure data from biomarker and questionnaire data. We were able to use two complementary age-appropriate instruments to measure ADHD–related behaviors. The CBCL screens for various childhood behavior problems, including ADHD [53]. The CPRS tests specifically for ADHD and related problem behaviors and is intended to be more diagnostic than the CBCL [54]. Due to the prospective nature of our cohort study we were able to assess the association between environmental exposures sustained prenatally and future development of ADHD-related behaviors in childhood.

A limitation of the study is that unmeasured factors such as other pollutants, stress, and noise may have contributed to residual confounding. In addition, the number of children with moderately to markedly atypical outcomes on the CPRS (cases) was small, resulting in fairly wide confidence intervals around the odds ratios. However, the confidence intervals around the effect estimates for the continuous outcomes are much tighter. Although of interest, we

did not have complete data on exposure to lead or mercury and were unable to account for this in our models. We were also unable to evaluate the effects of individual postnatal PAH metabolites that may have differing toxicities; however benzo[a]pyrene is an important, toxic member of the class of PAH. Finally, generalizability was reduced by the ethnicity restriction of our cohort (African-American and Dominican) and our exclusion of active smokers, illicit drug users, and women with pre-existing disease.

Conclusions

In conclusion, this study provides evidence that early exposure to environmental PAH may contribute to ADHD behavior problems in children. The results require confirmation but are of concern since children with ADHD are at greater risk of risk-taking behaviors [84], poor academic performance [85], and lower earnings in adulthood [86,87]. ADHD imposes large costs on society, estimated to range between $36 billion and $52 billion annually [67,68].

PAH are widespread in urban environments worldwide largely as a result of fossil fuel combustion. Fortunately, it is possible to reduce airborne PAH concentrations using currently available pollution controls, greater energy efficiency, the use of alternative energy sources, and regulatory intervention to control polluting sources.

Acknowledgments

Funding was provided by the National Institute for Environmental Health Sciences (NIEHS) and the U.S. Environmental Protection Agency (US EPA): NIEHS/EPA P01ES09600/R82702701, NIEHS/EPA P01ES09600/RD832141, NIEHS/EPA P01ES09600/RD834509, NIEHS R01ES08977. This publication was also made possible in part by US EPA grants RD832096, the John & Wendy Neu Family Foundation, the New York Community Trust, Trustees of the Blanchette Hooker Rockefeller Fund, and an anonymous foundation. Funding from all the institutions listed was used towards the design and conduct of the study; collection, management, analysis, and interpretation of the data; and the preparation, review, and approval of the manuscript. Its contents are solely the responsibility of the grantee and do not necessarily represent the official views of the US EPA. Further, US EPA does not endorse the purchase of any commercial products or services mentioned in the publication. Findings expressed in this paper are the opinions of the authors and do not necessarily reflect the official opinion of the Centers for Disease Control and Prevention.

Analysis of PAH metabolites was conducted at the Centers for Disease Control and Prevention, National Center for Environmental Health, Division of Laboratory Sciences, 4770 Buford Highway, Atlanta, Georgia 30341, United States, in the laboratory of Andreas Sjodin, PhD. We also thank Joanne Chin, MFA, at the Columbia Center for Children's Environmental Health, 722 W. 168th Street, New York, NY 10032, United States, for assistance in manuscript preparation.

Traffic-related air pollution and brain development

Nicholas Woodward[*], **Caleb E. Finch**, and **Todd E. Morgan**

Davis School of Gerontology and the Dornsife College, Department of Biological Sciences, University of Southern California, 3715 McClintock Ave, Los Angeles CA 9009-0191, USA

Abstract

Automotive traffic-related air pollution (TRP) imposes an increasing health burden with global urbanization. Gestational and early child exposure to urban TRP is associated with higher risk of autism spectrum disorders and schizophrenia, as well as low birth weight. While cardio-respiratory effects from exposure are well documented, cognitive effects are only recently becoming widely recognized. This review discusses effects of TRP on brain and cognition in human and animal studies. The mechanisms underlying these epidemiological associations are studied with rodent models of pre- and neonatal exposure to TRP, which show persisting inflammatory changes and altered adult behaviors and cognition. Some behavioral and inflammatory changes show male bias. Rodent models may identify dietary and other interventions for neuroprotection to TRP.

1. Introduction

Air pollution from fossil fuel combustion is increasingly recognized for its globally adverse effects on health throughout life. We focus here on traffic-related air pollution (TRP) from roadways in urban settings, for which there is strong epidemiological association with cardiovascular and pulmonary morbidity and mortality [1-4]. Moreover, TRP shows increasing evidence for impact on the brain. Thus, pre- and neonatal developmental exposure to TRP increases risk for low birth weight, and numerous cognitive detriments, including autism spectrum disorders (ASD), schizophrenia, delayed development and cognitive impairment [5-8]. The risks for these disorders are especially high during development, and pollution exposure during gestation can alter development and create lifelong deficits.

First, we discuss epidemiological data on the effects of TRP exposure during gestational development, including impaired fetal growth, as this is often associated with cognitive defects, and the effects of TRP exposure on later life cognition are reviewed. Rodent models are evaluated, as well as the relevant data produced from those models in this nascent field.

2. Overview of TRP

We review two broad groups of TRP: the airborne particulate matter (PM) and the vapor (gaseous) phase, with emphasis on the particulate matter component of TRP. Urban TRP PM is a complex and heterogeneous mixture that includes residues from fossil fuel combustion, organic chemicals, trace metals, nitrate, and sulfate. There are also airborne components from brake linings and the vehicular chassis, as well as roadway components and dust. The recognized size classes of airborne PM range from coarse PM (> 10 μm diameter) to microscopic classes with aerodynamic diameters less than 2.5 μm ($PM_{2.5}$) and 0.1 μm, ($PM_{0.1}$). For each class, primary emissions are transformed from exposure to sunlight and atmospheric ozone and nitric oxides during diurnal and seasonal cycles. While coarse PM are largely trapped by the upper airways, smaller PM can impact the brain directly from olfactory neurons in the nasal mucosa, as well as by systemic effects from the lower airways [9]. The smaller PM sizes are associated with many pathological effects of air pollution [10,11]. Although some studies lump the two smaller size classes under $PM_{10,}$ all three categories have notable adverse effects, as well as different distributions in space and dispersion characteristics.

Of the three categories of particulate matter, $PM_{2.5}$ (fine PM) has received the most attention, with current US EPA standards [12] of 12 $\mu g/m^3$. The EPA has not yet addressed $PM_{0.1}$ (UFP, or ultrafine particulates). This class of TRP warrants attention in public health because of experimental evidence for its greater cytotoxicity [13,14], potentially due to the greater penetration through cell membranes [15]. One reason UFP has not been fully appreciated is due to monitoring technology of PM based on weight and not particle number, where it is a large percentage of the total PM. We note alternate terminology of nanoscale PM, $PM_{0.2}$, which encompasses a larger portion of the ultrafine particles, and is considered alongside UFP in this review. UFP is associated with numerous adverse health effects, and comprises the majority of all PM in combustion-derived exhaust [15]. Their small size facilitates the crossing of physiological barriers, including the blood-brain barrier and the placenta as discussed below [6,9,16].

For discussion of developmental exposure, we briefly note that adverse health effects of air pollution exposure increase with closeness to major road [10,17]. UFP was reduced by approximately 80% at a distance of 150 meters from the roadway [11]. Neither $PM_{2.5}$ nor PM_{10} decreased substantially within 150 meters [18], and are decreased by less than 20% at a distance of 400 m vs. 50 m from a roadway [19]. The rate of dilution of UFP was correlated with increased cardiopulmonary mortality, inversely with distance from roadways [10].

3. Epidemiology

3.1. Low birth weight

Because developmental cognitive defects are often associated with fetal growth retardation, it is important that TRP can impact fetal growth. Associations between air pollution exposure in gestation and impaired fetal growth continue to emerge. In particular, $PM_{2.5}$ is associated with low birth weight (LBW) (< 2,500 g), preterm birth, and small gestational

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

size [20]. However, the critical period for exposure during pregnancy and threshold for these effects remain undefined. We discuss select large-scale studies of PM exposure during gestation. Also see the comprehensive review of Shah and Balkhair [20].

A large Los Angeles based study (n = 220,528) showed 5% greater risk of LBW from $PM_{2.5}$ exposure, with a range of 2.4 μg/m^3 [7]. Other studies used ultrasound to determine the gestational timing of LBW association with air pollution. The largest of these studies (17,660 pregnancies) showed the most consistent association PM_{10} exposure during days 91–120 of pregnanc y, where high PM_{10} correlated with smaller abdominal circumference, heard circumference, and femur length [21]. Though this study did not find association with nitric oxide (NO_2) exposure, other studies associated exposures of NO_2 > 38 μg/m^3 with reduced fetal size, femur length, and biparietal distance, even when high NO_2 was recorded only for weeks 12–20 [12 ,23]. Other studies associated elevated PM_{10} exposure with preterm birth [23,24,25]. A potential mechanism underlying LBW is oxidative stress from maternal exposure during pregnancy to TRP, e.g. increased placental DNA adducts [26].

Obesity is also showing association with air pollution components, which may contribute to diabetes and the metabolic syndrome [27]. Adults (n = 5,228) exposed to NO_2 showed 17% higher risk of diabetes mellitus in the top vs. lowest quintile, differing by 4 ppb [28]. There are also correlations between PM_{10} exposure and the white blood cell count, a marker for systemic inflammation [29].

3.2. Cognitive changes

Epidemiological studies of TRP show negative associations with adult cognition [5,30,31] and brain development [5,30,31,32]. In particular, pre- and postnatal exposure to urban TRP is correlated with autism spectrum disorders (ASD), schizophrenia, and impaired cognitive development. We briefly summarize these findings.

ASD was associated with local gradients in components of TRP, mainly $PM_{2.5}$. Two studies utilizing the California based CHARGE (Childhood Autism Risks from Genetics and the Environment) database found about 2-fold higher odds ratio (OR), for development of ASD, when living near a freeway during the 3rd trimester, and at delivery (< 309 m defined as near, with > 1,419 m as reference group) [31,33]. Exposure during the first postnatal year was associated with 3-fold higher OR for ASD [31]. $PM_{2.5}$ had an OR of 2.08 for gestational exposure, and 2.12 for exposure in the first year of life [31,33]. Similarly, the Nurses' Health Study, a national sample, sho wed an OR of 2.0 for prenatal diesel particulate exposure, top vs. bottom quintile ($PM_{2.5}$ 4.40 vs. 0.60 μg/m^3) [34]. Contrarily, a study of Swedish twins did not find association of TRP with ASD (PM_{10} 3.3–4.2 μg/m^3); however, this study measured a broader size range of particles [2]. An analysis of 35 pollution components showed higher OR for ASD after exposure to methylene chloride, quinolone, and styrene, but not after diesel PM, or polycyclic aromatic hydrocarbons (PAHs) [35]. The authors noted that the control group had impairments of speech and language, which may have biased the results towards null findings.

Schizophrenia risk is also sensitive to TRP in top vs. bottom quintiles of urbanicity (population density) during gestation, but not during childhood [30]. A study of traffic

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

volume and urbanicity (household crowding, social stressors) concluded that only traffic volume exposure at birth predicted schizophrenia (OR of 4.40 for the top vs. lowest quintile of traffic exposure) [5]. Both studies agree that only exposure during the gestational period correlated with increased risk.

TRP exposure during development is also associated with subclinical cognitive effects, including lower mental development, increased anxiety and depressive behavior, and attentional problems [32,36,37]. A Spanish national study showed decreased mental development for infants of mothers exposed during pregnancy to elevated NO_2 and benzene [36]. Importantly for potential interventions, this association was attenuated in mothers who self-reported a high intake of antioxidant rich foods. We also note the benchmark study of Perera et al. 2003 [38] on PAH levels for Hispanics and African Americans in New York City, which was the first to utilize personal monitors for PAH levels, with greater precision than citywide measurements. Developmental measurements at birth associated high PAH (> average 3.7 ng/m^3 in maternal blood) with a 9% decrease in birth weight, and a 2% decrease in head circumference. The OR for cognitive developmental delay, at 36 months from PAH exposure during gestation was 2.89, for the top vs. bottom quintile [37]. By age 6–7 years, individuals in the top exposure quintile were more anxious and depressed (OR 1.45), with more attentional problems (OR 1.28, top vs. bottom quintile) [32]. For DSM-IV oriented anxiety problems, the OR was a striking 4.59 [32].

4. Rodent models

4.1. Experimental approaches

Several labs have developed rodent models studying the developmental effects of TRP exposure, but no single paradigm has become widely accepted. The main findings (Tables 1–6) include effects on brain morphology, behavior, inflammatory markers, and neurotransmitters. Four experimental paradigms are currently used (Table 1): direct diesel exhaust inhalation, diesel exhaust particle (DEP) oropharyngeal aspiration, the Concentrated Air Particles delivery System (CAPS), and filter-trapped nano-sized ambient reaerosolized particles. Most studies used inhalation, while one lab used direct oropharyngeal aspiration of DEP.

Diesel exhaust: Pregnant mice were exposed to the whole exhaust stream from a diesel engine, diluted to concentrations ranging from 0.171–3.0 mg/m^3. Auten et al. 2012 [47] and Bolton et al. 2012 [48] utilized a 6.4 hp direct injection single cylinder 320-cc Yanmar L70V diesel generator, operating at a constant 3600 rpm. Yokota et al. 2009 [39] used a 2369-cc diesel engine, operating at 1050 rpm. The exhaust includes volatile gaseous components, notably CO, SO_2, and NO_2. Unlike other exposure paradigms, these particles are not filtered by size, and retain native charges. The direct diesel exhaust paradigm is missing other real world pollutants from vehicular traffic, e.g. rubber from tire erosion, brake lining debris, and reaerosolized dust from roadways. Moreover diesel engine exhaust can represent only one type of vehicle, and the particles are being directly emitted and thus did not undergo the secondary reactions from heat and sun exposure, which develop as a function of time after emission.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Diesel exhaust particles (DEP)

Oropharyngeal Aspiration: (Auten et al. 2012 [47]) This is the only non-inhalation paradigm used in the prenatal studies. Diesel exhaust particles are collected from a single cylinder diesel engine, and then 50 μg of diesel exhaust particles (DEP) are suspended in 50 μL of PBS with 0.05% Tween-20 and delivered by oropharyngeal aspiration. Importantly, this delivery method bypasses nasal inhalation.

Reaersolized Inhalation: (Hougaard et al. 2008 [40]) Obtained from the National Institute of Standards and Technology, Standard Reference Material 2975, these particles are obtained from a diesel powered forklift, and are re-aerosolized for inhalation delivery [40,41]. Importantly, the re-aerosolized DEP, like the resuspended DEP for oropharyngeal aspiration, lack gaseous and volatile components. Also, because the particles are suspended in water, they are depleted of insoluble PM. Elimination of insoluble particulate matter is of special relevance, as this includes black carbon and polycyclic aromatic hydrocarbons (PAHs).

CAPS (Concentrated Ambient Particle System): Ultrafine fractioned particulate matter is concentrated next to a roadway for direct real time delivery at 10–20 times ambient concentration [42]. CAPS maintain ambient components, including gases and volatiles, and the native charges of the particles. Importantly, condensing the particles does not alter their natural size distributions, and does not amplify aggregation [13,42]. Limitations of this system are its dependence on the current traffic patterns, which fluctuate diurnally and seasonally.

Filter-trapped nano-sized PM from urban TRP: This paradigm, developed by Constantinos Sioutas at the University of Southern California [43], collects ambient air particulate matter, $PM_{0.2}$, on the roadside next to a high traffic source with a high-volume ultrafine particle sampler on 0.2 μm pore Teflon filters. Collections are made for 4–6 weeks in the fall to encompass the range of temperatures and moisture in Southern California [44,45]. The collection is continuous and includes secondary transformations during the diurnal cycle. Besides combustion products, the sample includes reaerosolized roadway dust, and traces from brake lining and tire erosion that are < 0.2 μm. The filters are sonicated in distilled water to yield a suspension, which is stored frozen until use. The reaerosolized PM has average particle size of 60 nm at a density of 350 $\mu g/m^3$, which is about 25× greater than ambient concentrations of that size range of particle [44,45]. The resuspension lacks ambient gases and is depleted in water insoluble organic species including PAHs and black carbon [43]. We designated these materials as nPM (nanoparticulate matter) in distinction from the size class of ambient UFP in the literature. After re-aerosolization, rodents are exposed to nPM together with ambient pollutants in the exposure room, which are 35–50% below outdoor ambient levels, while control animals have this air filtered by HEPA filters.

In summary, each experimental paradigm represents trade-offs. While DE is the most readily obtained, they are model emissions of one engine type and lack secondary atmospheric transformations of ambient pollution. The CAPS fully capture TRP for PM, gases, and volatiles, but vary diurnally and seasonally. The nPM capture diurnal variations, but the

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

resuspension is deficient in black carbon (BC) and PAH among other water insoluble organic compounds.

4.2. Body weight

Epidemiological findings of air pollution on birth weight are corroborated in some rodent models (Table 2). Mice exposed to 3.0 mg/m^3 DEP had decreased fetal weight as early as gestational day (GD) 18 (equivalent to the human third trimester) [46]. Several studies observed a weight decrease four weeks after birth in mice exposed to DEP (Table 3) [40,47]. Finally, two studies observed a reversal later in life, with increased weight at four months of age in mice [48], and at eight weeks in rats [49]. Decreased weight at weaning [40,47], combined with increased weight later in life [48,49], corresponds with previously documented rebounding in weight after a prenatal stressor [50]. Air pollution also has an additive effect on weight when exposure occurs in utero, followed by a high fat diet (HFD = 45% calories from fat) after birth (Table 4) [48,51]. The prenatal DEP + HFD treated mice showed significant weight gain over high fat diet alone, a compounding effect similar to what was observed for inflammatory responses (increased cytokines, microglial activation) [48,51]. Males in both replicates showed greater weight gain from treatment [48,51]. However, females showed 4.4× greater weight gain for the first experiment [48], and no change in the second [51]. Notably, the first experiment used diesel exhaust inhalation, while the second employed oropharyngeal aspiration of DEP, which excludes gas components. Thus, it is possible that either a species lost in the conversion to suspended diesel particles, or the inhalation delivery route caused the weight gain. The high fat postnatal group showed insulin resistance with elevated serum insulin in the males [48,51]. Females showed only a change in serum leptin, while males did not show any differences from pollution exposure.

Exposure to highly polluted ambient Beijing air (75.3 μg/m^3) caused, worsened lipid profiles and weight gain in both rat mothers and offspring [49]. Pregnant dams had higher low-density lipoprotein (LDL), total cholesterol, triglyceride, and overall weight. Pups had increased weight at eight weeks, and worsened lipid profiles, with increased LDL, total cholesterol, and triglyceride, and decreased in HDL. Rodent models also corroborated mid-life and gestational weight effects [27,48,51,52].

4.3. Behavioral changes

Behavioral changes from developmental pollution exposure include cognitive and locomotor deficits (Table 2). Cognitive deficits include depressive symptoms, impaired short-term memory, and decreased response rates for fixed interval sixty-second (FI60) reward tests [53,54]. Mice exposed in utero to nPM showed increased immobility on a tail suspension test, which is a marker for depression [54]. Only males were vulnerable, with a decreased delay until first period of immobility, and 2.6× longer immobility versus control, which implicates activation of the amygdala [55,56]. Correspondingly, prenatal exposure to DEP (maternal oropharyngeal DEP aspiration) increased adult amygdala levels of monoamine neurotransmitters (dopamine, dopamine metabolites, and serotonin) [57]. However, the oropharyngeal DEP model did not alter adult forced swim performance, another marker for depression considered equivalent to tail suspension [48]. This discrepancy could be due to the different age at assessment (8 mo vs. 4 mo), or the different pollutant models.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Impaired short-term memory was observed in neonatal mice exposed to CAPS, from postnatal day (PND) 4–7 and 10–13 and assessed at 2 months of age by the nov el object recognition test. In the one-hour posttest, CAPS exposed mice spent more time with the familiar versus novel object, indicative of impaired short-term memory [53]. The FI60 test, a model of impulsivity, showed decreased response and run rates, but only for males [53]. Despite smaller overall response rates, there was no significant difference in learning. In a separate experiment, conducted with the same exposure protocols, a secondary dose of pollution from PND 56–60 caused deficits in a fixed interval waiting for reward test, a classic model of impulsivity control [58]. These experiments included CAPS exposure on postnatal days 4–7 and 10–13. The sensitivity to neonatal e xposure is important because neonatal rodent nervous systems are relatively less mature compared to humans [59].

Deficits in short-term memory of neonatal CAPS exposure may be mediated by glutamatergic changes. Glutamate levels in the hippocampus, which is critical for spatial learning and memory, were increased 1.26-fold in the male CAPS exposed mice [58]. Though the effect returned to baseline by eight weeks of age, the transient glutamatergic increase during development could cause persisting effects, including excitotoxicity. Detailed studies of hippocampal circuit functions, e.g. LTP, and synaptic density are needed. Increased inflammatory cytokine levels (Il-6, IL-1b, TNF-a) are also relevant to behavioral deficits through their impact on synaptic plasticity. These cytokines showed complex changes in different brain regions in mice exposed to neonatal CAPS [58,60]. For example, TNF-a modulates glutamate, and potentiates the cell to glutamatergic excitotoxicity [61], which could alter short-term memory later in life.

Locomotor deficits from prenatal exposure to pollutants include decreased spontaneous motor activity and impaired balance (Table 4) [39,48,57,62]. Intriguingly, only males have shown decreased spontaneous motor activity in studies from several labs that include ages from 5 weeks to 5 months [39,60,62]. Decreased spontaneous motor activity at age 2 months in CAPS studies was only observed when paired with a second treatment from PND 56–60 (Table 4) [53]. Balance was impaired on the rotating rod test in prenatally exposed male mice at 5 weeks [57]. These mice also had decreased latency in the cliff avoidance test [57]. The impaired performance on these two balance tests is not attributable to differences in body weight [57]; only Bolton et al. 2012 reported weight differences [51]. We note that a shift from direct exposure to diesel exhaust to the oropharyngeal DEP in the same lab did not to replicate these effects [51].

4.4. Gross brain morphology

Gross brain weight has not shown sensitivity to prenatal exposure to nPM [54]. However, one study of neonatal exposure to concentrated ambient TRP reported gross enlargement of the lateral ventricles, particularly in males [63]. The nPM prenatally exposed mice revealed no gross brain abnormalities, but quantitation is needed. Cerebral vasculature has just begun to receive attention in air pollution models. After maternal intranasal exposure to black carbon, young adult mice had focal induction of GFAP in astrocyte endfeet on capillary endothelia and altered arterial macrophage granules [64]. These reports point to structural changes that could underlie cognitive dysfunctions from prenatal exposure.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

4.5. Neuronal changes

We note a major gap between the body of epidemiological evidence for TRP associations with brain development and the scant information on neuronal changes in animal models of prenatal TRP exposure. Reports on neuronal changes are scattered among different neurotransmitters, often in different brain regions, giving little cohesion of results (Table 5). Dopamine levels in the cerebral cortex illustrate the diversity. Mice exposed to prenatal diesel exhaust had lower cortical dopamine for males at 3 weeks, but no change at six weeks [57]. However, the same exposure paradigm in a different lab showed increased cortical dopamine at 5 weeks [62]. These studies used > 5-fold different levels of DEP density. The turnover of dopamine, estimated by the ratio of the catabolite DOPAC to dopamine, (DOPAC: DA) was higher in neonatally CAPS exposed male mice at two and eight weeks [58].

Neurotransmitter changes reported for adult rodent TRP exposures have not been borne out by prenatal exposures, potentially indicating different mechanisms. We observed decreased glutamate receptor 1 (GLUR1) in the hippocampus in mice exposed to nPM at age three months [43]. However, prenatal exposure did not alter hippocampus GLUR1 at eight months [54]. Neonatal exposure to DEP transiently increased hippocampal glutamate at two weeks, with return to baseline by eight weeks [58].

Cortical neurons harvested from one day old pups prenatally exposed to nPM showed impaired differentiation and neurite initiation, with fewer stage 3 neurons, compared to controls [54]. These pilot studies give a model for linking developmental exposure to alterations in neurons and glia.

4.6. Inflammatory changes

Inflammation may be a major mediator of maternal systemic and placental responses to air pollution exposure [60]. Systemic inflammation in the mother increases circulating inflammatory cytokines, influencing the development of the fetus, through methods such as the activation of microglia (Table 6) [48,65]. As noted above for neuronal changes, there is a need for similar protocols across labs in the investigation of inflammatory effects.

Prenatal exposure of mice to diesel exhaust rapidly increased cytokines (IL-1b, IL-6, IL-10, and TNF-a) on GD18 [47,48]. Microglial activation is suggested by increased chemokines CCL2/MCP-1 and CX3CL1/Fractalkine [48]. After CAPS neonatal exposure, proinflammatory cytokines (IL-6, IL-1b, TNF-a) were decreased at 2 weeks in males [58]. However, by eight weeks, a full month after the cessation of exposure, IL-1b and TNF-a rebounded to levels 1.4-fold above control's in midbrain[58]. Females showed a different time course, with little upregulation immediately following exposure, yet still showing delayed increases a month later. This effect was brain region specific: unlike the midbrain, the striatum had lower cytokines at the same times [58]. These sex differences in cytokine responses between different brain regions clearly show that inflammatory effects of pollution exposure must be studied in terms of brain pathways and cannot be generalized to the entire brain.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Glial inflammatory responses are detected by the astrocyte specific GFAP (intermediate filament glial fibrillary acidic protein) and the microglial marker of IBA1 (ionized calcium-binding adapter molecule 1). These responses were observed in neonatal exposures, and prenatal exposures compounded with a secondary stimulus. Neonatal mouse exposures from PND 4–7 and 10–13 increased GFAP in the hippocampus, corpus callosum, and anterior commissure in females, while males responded with decreased GFAP [58]. These measurements were made immediately following exposure, at two weeks. IBA1 was upregulated in the hippocampus and corpus callosum for males, at eight weeks and 9 months, respectively [53,58]. Females showed no change for IBA1. Adult mice of several genotypes showed brain inflammatory responses, with induction of IL-1a and TNFa, and activation of microglia and astrocytes [13].

Inhalation of prenatal diesel exhaust, as well as oropharyngeal aspiration of DEP, did not elicit any changes in GFAP or IBA1 in mice, examined at six months of age [48,51]. However a high fat diet (HFD) starting at 4 months and lasting for six weeks, along with the prenatal DE exposure, increased IBA1, but not GFAP [48]. IBA1 was increased in hypothalamus, dentate gyrus, amygdala, and the CA1 of the hippocampus for males [48]. Females showed changes only in the hypothalamus and dentate gyrus [48]. This upregulation of IBA1 supports the hypothesis of air pollution exposure during gestation as an enhancer for later life environmental insults: the DE+HFD group responded more than either treatment alone, with changes in brain regions that did not change with only one of the treatments (Table 3). The two-hit hypothesis postulates that the first insult primes the system [48,60]. While inflammation may not be activated by a single insult, the second inflammatory challenge may cause a disproportionately larger response.

4.7. Sex differences

Sex differences are apparent in rodent responses to prenatal exposure, with greater male vulnerability observed. For open field activity, only male mice showed deficits [48]. For the tail suspension test, a measure of depressive behavior, only males were responsive, with no effect for females [54]. Further sex differences were shown in secondary treatments (Table 3). Release of inflammatory cytokines is profoundly affected by sex, a trend even more pronounced with the addition of a secondary insult. When prenatal diesel exposure is combined with either six weeks HFD, or nest restriction from gestational day (GD) 14–19, male mice show significant effects in numerous cytokines and chemokines, while females show no changes [51,66]. The combination of prenatal diesel exposure and adult high fat diet increased serum insulin, insulin resistance, and IL-1b, again only in male mice [51]. Brain inflammatory proteins CD11b, TLR4, and CXC3CR1 were increased only in males [51]. Likewise, only males had increased peripheral macrophage infiltration in the hypothalamus [51]. Furthermore, for nest restriction paired with diesel exposure, only males showed decreased contextual fear recall, and changes in brain TLR4, caspase-1, IL-1b, and IL-10 [28]. Finally, in the combination of PND 4–7, 10–13, and 55–60 CAPS exposure, only males showed increased IBA1 staining in the corpus callosum [53]. These experimental findings demonstrate greater male vulnerability to pollution exposure, especially when combined with a second insult.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

4.8. Nanoparticles in utero

One hypothesis for the mechanism underlying air pollution's physiological effects is unique to the nanoscale particulate matter component. It is possible that the particles might be able to cross the placental barrier to directly interact with the fetus, which develops a blood-brain barrier by gestational day 16 [67]. There is experimental evidence for transplacental transfer of nano-size PM. Titanium dioxide nanoparticles (25–70 nm dia) subcutaneously deli vered to pregnant mice on GD 3, 7, 10 and 14, were detected in male brains and testes six weeks postnatally [68]. Thus, model nanoparticles can cross both the maternal placenta and the blood-brain barrier of the developing fetus. *Ex vivo* models with human placenta and polystyrene beads show strong size dependency, with 50 and 80 nm beads rapidly crossing the placenta, possibly by simple diffusion; larger beads > 240 nm do not cross [69]. However, this *ex vivo* model does not represent potential modification of PM by proteins and lipids, which create a bio-corona, altering the movement of the nanoparticles [70]. Engineered nanoparticles of this size show 1000-fold range of translocation to the brain (0.00006% to 0.03%) [63,71]. Although particles may cross secondary barriers (placenta, blood-brain), their inhalation or ingestion does not necessarily allow transport to these secondary barriers. This is of relevance because most experiments inject the particles into the animal, bypassing the lungs. The small size of nanoparticles is important, as particles < 34 nm rapidly translocate from lung to mediastinal lymph node [72]. Notable, negatively charged particles accumulated in secondary organs more than positively charged particles [73].

The placenta may be more vulnerable to nanoparticle entry later in gestation, when the placental wall has thinned and is more vascularized, but also early in gestation before the placenta is fully formed [50]. The period after the placenta is formed, but before maternal-fetal circulatory systems are fully developed, could be less vulnerable to pollution exposure, due to minimal blood flow to the fetus. Nanoparticles may even cause fetal damage without penetrating the placenta, e.g. *in vitro,* nanoparticles can cause DNA damage even when they do not cross a cell barrier [74]. We note that these are not exclusionary hypotheses, and both may potentially be occurring.

4.9. Protective measures

In the urban realities of 21st Century populations, it is not possible to prevent prenatal exposure to TRP by restricting household or school proximity to roadways. Thus, we must consider other means to limit detrimental effects of prenatal TRP exposure. Diet optimization may be a pragmatic approach. As a precedent, higher maternal consumption of fruits and vegetables was associated with better mental development in exposure to benzene and NO_2 [36]. Supplementation with anti-oxidants, e.g. the omega-3 fatty acid, docosahexaenoic acid, may blunt TRP induced oxidative stress [75]. While such interventions could attenuate effects, real solutions must come from technical advancements to lower the use of fossil fuels. Combustion engines can be made more efficient, while petroleum itself can be replaced by methanol, which produces fewer particles during combustion [76].

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

5. Conclusions

Traffic related air pollution is correlated with numerous detrimental health outcomes: increased cardiovascular mortality from adulthood exposures, and low birth weight and cognitive disorders from gestational exposure. These epidemiological observations are largely verified in animal models. The field is emergent with only a handful of labs worldwide studying animal models. There are huge gaps in the understanding of how TRP affects the brain. Specifically, neuronal changes, both in protein and morphology, and potential epigenetic modifications, are lacking. Another challenge comes from the different experimental paradigms between labs, particularly the source of PM and delivery regimen. Relatively few observations have been corroborated across labs. Even so, there is a clear trend for numerous adverse cognitive effects from pollution exposure during development, and future studies hold many promises.

Table 1

Air pollution exposure sources

Exposure study	Methods	Particulate matter size and composition	Volatiles	Non-tailpipe pollution	Secondary aerosols
Diesel exhaust					
Direct from diesel engine Bolton et al. 2012 [48]	Auten et al. 2012 [47]	18-200 μm; extractable organic matter, 39.8%	Yes	No	No
Sugamata et al. 2006 [77], Fujimoto et al. 2005 [46], Yokota et al. 2009 [39], Yokota et al. 2013 [57], Suzuki et al. 2010 [62]	Umezawa et al. 2011 [78]	All size particles	CO, 2.67 ppm; NO_2, 0.23 ppm, SO_2, < 0.01 ppm	No	No
Diesel exhaust particles Bolton et al. 2013 [67], 2014 * [51]	Auten et al. 2012 [47] Hougaard et al. 2008 ** [40]	18-200 μm	No	No	No
Traffic-related air pollution					
Ambient Air Wei et al., in prep. [49]		All size particles	Yes	Yes	Yes
Concentrated Ambient Particle System (CAPS)	Allen et al. 2013 [79], 2014a [53], 2014b [58]	< 100 nm dia.	Yes	Yes	Yes
Filter-trapped nano-sized PM (nPM) Davis et al. 2013 [54]	Morgan et al. 2011 [43]	< 200 nm dia. Filter-bound, re-aerosolized.	No	Yes	Yes

Non-tailpipe pollution includes brake dust, tire erosion, and roadway dust. Secondary aerosols arise from alterations of particulate matter by temperature, sunlight, humidity, ozone etc.

*Particles delivered by oropharyngeal introduction.

**Diesel exhaust particles reaerosolized for inhalation.

ABSTRACT

Accumulating evidence from both human and animal studies show that brain is a target of air pollution. Multiple epidemiological studies have now linked components of air pollution to diagnosis of autism spectrum disorder (ASD), a linkage with plausibility based on the shared mechanisms of inflammation. Additional plausibility appears to be provided by findings from our studies in mice of exposures from postnatal day (PND) 4–7 and 10–13 (human 3rd trimester equivalent), to concentrated ambient ultrafine (UFP) particles, considered the most reactive component of air pollution, at levels consistent with high traffic areas of major U.S. cities and thus highly relevant to human exposures. These exposures, occurring during a period of marked neuro- and gliogenesis, unexpectedly produced a pattern of developmental neurotoxicity notably similar to multiple hypothesized mechanistic underpinnings of ASD, including its greater impact in males. UFP exposures induced inflammation/microglial activation, reductions in size of the corpus callosum (CC) and associated hypomyelination, aberrant white matter development and/or structural integrity with ventriculomegaly (VM), elevated glutamate and excitatory/inhibitory imbalance, increased amygdala astrocytic activation, and repetitive and impulsive behaviors. Collectively, these findings suggest the human 3rd trimester equivalent as a period of potential vulnerability to neurodevelopmental toxicity to UFP, particularly in males, and point to the possibility that UFP air pollution exposure during periods of rapid neuro- and gliogenesis may be a risk factor not only for ASD, but also for other neurodevelopmental disorders that share features with ASD, such as schizophrenia, attention deficit disorder, and periventricular leukomalacia.

1. Introduction

1.1. Air pollution exposure

Air pollution is a complex mixture of particles, gases, trace metals and adsorbed organic contaminants. Particle sizes range from coarse (2.5–10 μm) to fine (<2.5 μm) to ultrafine (UFP, <100 nm or 0.1 μm). Although not a significant component by mass, UFPs achieve orders of magnitude higher particle number concentrations and thus have more extensive surface areas that can adsorb toxic air pollutants (oxidant gases such as ozone, NO_X, organic compounds, transition metals) per unit mass. Ambient UFPs arise primarily from combustion of fossil fuels (i.e., motor vehicle traffic) (Lippmann et al., 2013). Levels of up to 50% of inhaled UFP are deposited in pulmonary alveolar regions of lung from where they can traverse the alveolocapillary barrier to access pulmonary interstitium and cross endothelial cells into blood circulation and subsequently impact other organs, including heart and brain, and thereby lead to more serious health consequences, which is why UFPs are considered among the most reactive elements of air pollution (Oberdorster et al., 1994; Brown et al., 2001). Deposition can also occur in the nasal cavity allowing translocation to brain (Elder et al., 2006; Hunter and Dey, 1998; Lewis et al., 2005).

Air pollution is a worldwide environmental health problem, to which exposures begin at gestation, and are cumulative over the lifespan. While air quality standards have clearly improved in many countries, even as of 2012, the U.S. Census Bureau estimated that approximately 142 million U.S. residents live in counties where regulated levels of various air pollutants exceeded

standards set by the U.S. Environmental Protection Agency (EPA). Further, ongoing urbanization trends and expanding road traffic in many areas of the world are predicted to further increase population exposures to UFP air pollution (Kumar et al., 2014). Currently, the U.S. EPA sets regulatory standards for levels of PM_{10} and $PM_{2.5}$. In addition to the fact that it represents a significant technological challenge, regulation of UFPs is said to await additional evidence of their toxicity. Considered in a global context, new studies ascribe 3.3 million premature deaths per year to outdoor air pollution (Lelieveld et al., 2015), and as of 2013, air pollution was listed as the 12th leading global risk factor for disability adjusted life year reductions (Forouzanfar et al., 2013).

1.2. Air pollution and brain

While the focus of air pollution research has long centered on cardiovascular and pulmonary systems, evidence now shows that air pollution also adversely impacts brain, and does so by mechanisms similar to those operative in lung, i.e., via inflammation and oxidative stress (Block and Calderon-Garciduenas., 2009). In children, various components of air pollution have been associated with impaired cognitive abilities (Harris et al., 2015; Suglia et al., 2008), deficits in attention-related behaviors (Chiu et al., 2013; Newman et al., 2013; Siddique et al., 2011), reduced mental development index and IQ scores (Perera et al., 2009), symptoms of anxiety/depression (Perera et al., 2006, 2012), decreased nonverbal reasoning ability (Edwards et al., 2010) and delayed psychomotor development (Guxens et al., 2015). Animal models confirm behavioral and CNS toxicity in response to gestational, postnatal and adult exposures to air pollution and/or its components (Block and Calderon-Garciduenas., 2009), including findings of depressive-like behaviors, impaired spatial learning and memory, reduced apical dendritic spine density and dendritic branching in hippocampus (Fonken et al., 2011), reduced numbers of hippocampal neuronal GluA1glutamate receptor subunits and altered neuronal differentiation of cortical neurons (Davis et al., 2013) and altered locomotor activity and levels of brain catecholamines (Suzuki et al., 2010).

Interestingly, the combined presentation of many of these specific impairments is consistent with the multifaceted nature of Autism Spectrum disorders (ASD) that has now reached a worldwide prevalence as high as 1–2% (Lai et al., 2014; Elsabbagh et al., 2012), with a clear bias towards males being more affected (Elsabbagh et al., 2012; Frazier et al., 2014; Van Wijngaarden-Cremers et al., 2014; Werling and Geschwind, 2013). Diagnosis of ASD relies on the identification of impairments of core behavioral features like social deficits, impaired communication, and repetitive/perseverative behaviors early in life. In fact, while the etiology of this highly intractable and extremely heterogeneous neurodevelopmental disorder remains unknown, numerous epidemiological studies of populations from different states within the U.S. and different countries now report associations of ASD diagnosis with components of air pollution, including residential distance from the freeway (Volk et al., 2011), ambient levels of metals (Roberts et al., 2013; Windham et al., 2006), aromatic solvents (Roberts et al., 2013; Windham et al., 2006; Kalkbrenner et al., 2010), styrene and chromium (Talbott et al., 2015), gases (Becerra et al., 2013; Jung et al., 2013; Volk et al., 2013), diesel exhaust (Roberts et al., 2013; Windham et al., 2006) and particulate matter ($PM_{2.5}$ and/or PM_{10}) (Becerra et al., 2013; Jung et al., 2013; Volk et al., 2013; Kalkbrenner et al., 2015; Raz et al., 2014). Some report increased odds ratios for ASD diagnoses in relation to levels of $PM_{2.5}$ (Jung et al., 2013; Volk et al., 2013; Raz et al., 2014), which includes UFPs, and/or NO_2, a surrogate for UFP (Beckerman et al., 2008). The one exception to such findings was a recent study that combined data across 4 cohorts, but, unfortunately, each cohort used different measures of autistic traits, effectively limiting power and comparability (Guxens et al., 2015).

Underlying reasons for an association of air pollution with ASD are not known, but several lines of evidence suggest that air pollution-induced inflammatory mechanisms during development could play a key role (Melillo and Leisman, 2009; Noriega and Savelkoul, 2014; Meldrum et al., 2013; Depino, 2013; Onore et al., 2012). For example, markers of inflammation are elevated in amniotic fluid (Abdallah et al., 2013), and through life (Gesundheit et al., 2013; Emanuele et al., 2010; Vargas et al., 2005) in ASD, consistent with a chronic inflammatory state in both periphery (Depino , 2013; Emanuele et al., 2010; El-Ansary and Al-Ayadhi., 2012; Naik et al., 2011) and brain (Vargas et al., 2005; Rose et al., 2012; Wei et al., 2011; Li et al., 2009). Increased cytokine levels, a consequence of inflammation, associate with severity of ASD diagnostic features (Ashwood et al., 2011). Correspondingly, multiple components of air pollution including diesel exhaust, fine as well as UFP, and toxicants adsorbed to particles, such as endotoxin (LPS), also produce inflammatory changes in brain (Bolton et al., 2012; Campbell et al., 2009; Hartz et al., 2008; Levesque et al., 2011a,b; Morgan et al., 2011; van Berlo et al., 2010).

Mechanistically, it has been proposed that air pollution-associated CNS pathology reflects interactive pathways that include systemic inflammation, as mediated e.g., by vagal nerve afferents (Oberdorster et al., 2004, 2009), in conjunction with direct effects of particulate matter on brain tissue (Block and Calderon-Garciduenas., 2009). Perhaps not surprisingly, levels of asthma, a disease associated with air pollution-induced inflammation (Wendt et al., 2014; Evans et al., 2014; MacIntyre et al., 2013; Gonzalez-Barcala et al., 2013), are substantially higher in children with ASD, consistent with common inflammatory mechanisms in lung and brain. In a nationally representative sample of 77,951 children, asthma was 35% more common in those with ASD after controlling for age, gender, body mass index, race, brain injury, secondhand smoke and socioeconomic status (Kotey et al., 2014); further the prevalence of both ASD and asthma has been increasing (Becker, 2007; Becker and Schultz, 2010).

Potential mechanistic links may also result from alterations in glutamate. Hyperglutamate function has been hypothesized to underlie ASD (Jacob et al., 2011), and air pollution impacts brain glutamate function (Davis et al., 2013). Both developing and adult microglia have functional glutamate receptors and microglial activation can engender glutamate release (Murugan et al., 2013; Takeuchi et al., 2005). Furthermore, glutamate release can also activate microglia, leading to a vicious cycle (Biber et al., 2007), and a potential mechanism of chronic inflammation.

This paper summarizes the results of a series of studies, including previously published findings and new data describing the impact of exposures of mice to concentrated ambient particles (CAPS) in the *ultrafine* particle (UFP) range that collectively appear to provide biological plausibility for an association between air pollution and ASD. As presented below, exposures of mice to real time, road inlet ambient concentrated (10–20*x*) UFP from postnatal days (PND) 4–7 and 10–13 (equivalent to human 3rd trimester (Clancy et al., 2007a,b; Rice and Barone, 2000), and a period of marked neuro- and gliogenesis (Bandeira et al., 2009), unexpectedly produced a pattern of developmental neurotoxicity notably similar to multiple hypothesized mechanistic underpinnings of ASD and other neurodevelopmental disabilities. Our exposure paradigm is highly relevant to human exposures as UFPs, considered the most reactive component of air pollution, occurred at levels consistent with high traffic areas of major U.S. cities.

2. Methods

Methods presented herein are for results not previously published; methods for findings presented in prior publications are in the corresponding cited references for those findings.

2.1. Animals, reagents, & exposures

Male and female C57BL6/J mice 8 weeks of age were purchased from Jackson Laboratories (Bar Harbor, ME) and allowed to acclimate in the housing room for 1 week prior to breeding. Mice were co-housed for 3 days and bred monogamously, after which males were removed and pregnant dams were singly housed with litters until weaning on PND21. Pups were exposed to filtered air (air) or concentrated ambient ultrafine particles (CAPS) using the Harvard University Concentrated Ambient Particle System (HUCAPS) fitted with a size-selective inlet and a high-volume ultrafine particle (UFPs, ≤100 nm) concentrator (10–20*x*) that takes in outdoor air at 5000 L per minute and concentrates ambient UFP, as previously described (Allen et al., 2013, 2014a,b,c). Exposures lasted for 4 h per day from 0700 to 1200 for 4 days per week from PND4-7 and PND10-13, with exposure timing corresponding to peak vehicular traffic outside the intake valve of the HUCAPS instrumentation. A condensation particle counter (TSI 3022A) provided particle counts. Mass concentration was calculated using idealized particle density (1.5 g/cm^3). A Scanning Mobility Particle Sizer (SMPS) was used to determine particle size distribution and median particle diameter + GSD. Due to the presence of the particle impactor in the HUCAPS system, mice in the CAPS exposure chamber may be held at a slightly higher negative pressure compared to the Air exposed mice in an adjacent chamber. Flow of CAPS-enriched and filtered air were both maintained at 35–40% relative humidity and 77–79 °F.

To preclude any effect of anesthetics on measured endpoints, brains were extracted following decapitation without sedation to assess the immediate and persistent effects of CAPS on white matter in the corpus callosum (CC), striatum (STR), and frontal cortex (FC). Brains were extracted and placed into 4% paraformaldehyde for 24 h and then cryoprotected in 30% sucrose until they sank. Brains were stored at 4 °C until they were sectioned on a freezing microtome at 40 μm thickness. Sectioned tissue was stored in sucrose- and ethylene glycol containing cryoprotectant and kept at −20 °C until immunostaining. To preclude litter-specific effects, only single pups/sex/litter were used in all of these studies. All mice used in this study were treated humanely and with regard for alleviation of suffering and approved by the University of Rochester Institutional Animal Care and Use Committee.

2.2. Particle size distribution and number and mass concentration

Exposures in this study were to concentrated ambient UFPs (≤100 nm). As previously reported (Allen et al., 2014a), mean particle diameter for these exposures was consistently below 100 nm; mean CAPS counts across the 8 days of exposures was approximately 200,000 particles/cm^3, and the mean particle mass concentration was 96 μg/m^3. These values are similar to values reported for expressway traffic in L. A. (Fruin et al., 2008; Westerdahl et al., 2005), and Minneapolis (Kittelson et al., 2004), and did not affect offspring body weights nor produce any overt toxicity.

2.3. Corpus callosum (CC) area determination

The size of the CC (approximate adult-equivalent Bregma range 0.74–0.2 mm) was determined by tracing the area of interest in at least 3 adjacent sections of slide-mounted brain using Neuroucida (MBF, Williston, VT). Software enumerated the area of interest in μm^2. Bregma for PND14 brains are approximate given that, to our knowledge, no atlas at that specific point of early postnatal brain development exists. Given difficulties in demarcation, all analyses of CC would also have included the cingulum, a primarily ipsilateral white matter tract lying above the CC that encircles the brain and provides communicative structure for components of the limbic system, critical to executive functions, decision-making and emotion. Dysregulation of cingulate bundle white matter development has also been linked to developmental disorders including ASD (Billeci et al., 2012; Ikuta et al., 2014), schizophrenia (Samartzis et al., 2014) and ADHD (Chiang et al., 2015).

2.4. Myelin basic protein immunostaining & image analysis

To determine the extent of myelination, every 4th section (PND14) or every 6th section (PND270) was stained for myelin

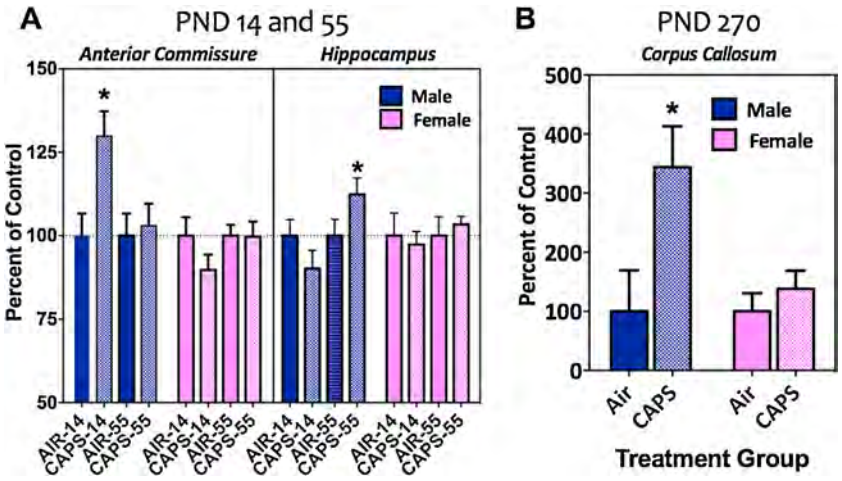

Fig. 1. CAPS exposure leads to male specific and time dependent increases in IBA-1. IBA-1 levels (group mean ± S.E.) as percent of time point control plotted separately for males and females for air and CAPS-treated groups at PND14 and PND55 in anterior commissure and hippocampus (Panel A) and at PND 270 in corpus callosum (Panel B). CAPS = concentrated ambient ultrafine particles; PND = postnatal day; air-14 = brains from air exposed offspring at postnatal day 14; air-55 = brains from air exposed offspring at postnatal day 55; CAPS-14 = brains collected at postnatal day 55 from offspring exposed to concentrated ambient ultrafine particles; CAPS-55 = brains collected at postnatal day 14 from offspring exposed to concentrated ambient ultrafine particles; brains collected at postnatal day 55 from offspring exposed to concentrated ambient ultrafine particles; * = significantlydifferent from corresponding time point control. *n* = 4–5/group.

basic protein (MBP) to assess global development and developmental trajectory of myelination in the CC (separately examining truncus (immediately posterior to the genu), medial external capsule and lateral external capsule), striatum, and frontal cortex. Briefly, brain sections were washed of cryoprotectant and placed into primary antibody for MBP (EMD Millipore; MAB386). Tissue was then placed into biotinylated secondary antibody (Vector labs; BA-9401; 1:200 dilution) for 1 hour and the stain was visualized using 3-3′-diaminobenzidine (DAB). Immunolabeled tissue was mounted onto Superfrost Plus micro slides (VWR; Radnor, PA; 48311-703) and cover-slipped using Cytoseal 60 (Fisher Scientific; Pittsburgh, PA; 23-244257).

Briefly, at least 3 images per region of interest were captured using an Olympus BX-41 brightfield microscope prior to image analysis. Expression of MBP was analyzed using Image Pro Plus 7.0 (Mediacybernetics) using segmentation and thresholding to estimate a percent area of the region of interest that was positive for MBP expression. For CC, percent of area myelinated was determined, whereas total relative units of myelination were measured in frontal cortex and striatum.

2.5. Statistical analyses

Statistical analysis was carried out using JMP11 (Cary, NC) with initial between groups ANOVAs that included all experimental factors (sex, group, PN) in full factorial designs. Main effects and interactions were then pursued in post-hoc *t*-testing as appropriate. p values ≤ 0.05 were considered statistically significant.

3. Results

3.1. Postnatal CAPS produces male-specific microglial (IBA-1) activation, reminiscent of inflammation and persistent microglial activation seen in ASD (Zeidan-Chulia et al., 2014)

We previously reported persistent and male-specific IBA-1-labeling (a marker for microglia) in male but not female CAPS-treated mice, as found in anterior commissure at PND14 and hippocampus at PND55 (Fig. 1A) and in CC at PND 270 (Fig. 1B), at which point microglial numbers were approximately 350% of air controls, even though exposures had ended at PND13 (Allen et al., 2014a,b). Microglial activation has been frequently observed in the context of ASD. For example, adult males with ASD showed increased binding of a microglial radiotracer in cerebellum, midbrain, pons, fusiform gyri and anterior cingulate and orbitofrontal cortices relative to age and IQ-matched healthy controls (Suzuki et al., 2013). Post-mortem brains from individuals with ASD showed increased astrocyte- and microglial specific markers in frontal cortex (Edmonson et al., 2014; Young et al., 2011; Morgan et al., 2010; Laurence and Fatemi, 2005). Inflammatory markers have also been detected in blood and urine in ASD (Vargas et al., 2005; Rossignol and Frye, 2014). Early microglial activation in developing CNS (Bilimoria and Stevens, 2014) could be the source of altered cytokine profiles where inflammatory signals have been shown to predominate (Masi et al., 2014). Collectively, these findings are consistent with a persisting inflammatory state.

3.2. Postnatal CAPS and male-biased ventriculomegaly (VM) and white matter tract disruption mimic aberrant white matter tract development and VM noted in ASD (Aoki et al., 2013; Keller et al., 2007)

We found a number of white matter tract changes in CAPS-exposed mice that are consistent with changes seen in ASD:

3.2.1. Lateral ventricle size

Unexpectedly, a *male-specific* VM of variable severity was seen (Fig. 2) in CAPS males, but not in Air males or in any CAPS females (Allen et al., 2014a). Quantitation of VM size was determined at 3 time points, and showed VM in males to be persistent, being statistically significantly lower than Air control values out to at least PND 270 (Fig. 3) (Allen et al., 2014a).

3.2.2. CC size and developmental trajectory

Because of the suggestion of a disrupted CC (Fig. 2E), CC area was quantified. Prior studies have indicated rapid postnatal growth in CC with adult-like patterns of connections by PND15 (Wahlsten , 1984). In our studies, female CC size was slightly smaller than males at PND14 (Fig. 4A and C), but larger at PND 270 (Fig. 4B and D) as shown in the trajectory across time (Fig. 4E; sex by time point, $F(1,41) = 57.9$, $p < 0.0001$), findings consistent with previous reports of greater increases in CC size in female rats between adulthood and middle age (Yates and Juraska, 2007) that is considered to reflect the initially larger number and greater size of myelinated axons in males (Yates and Juraska, 2007) and more

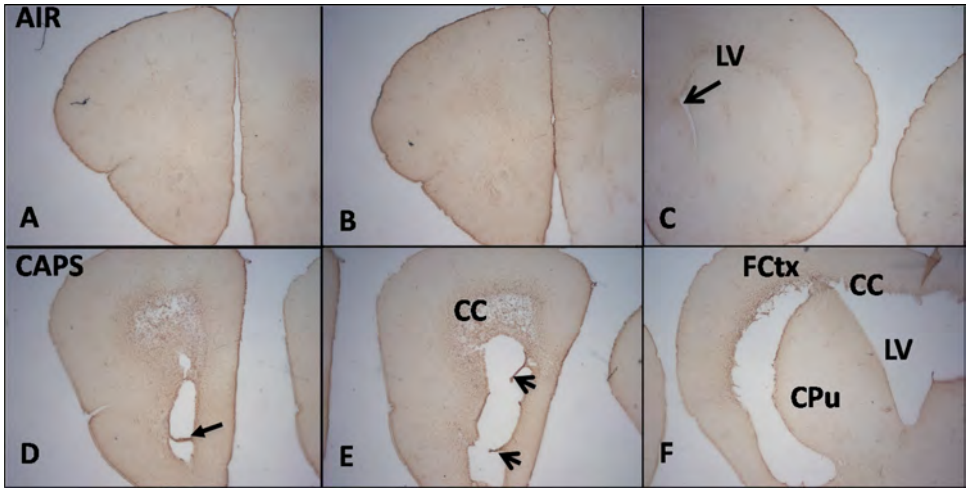

Fig. 2. CAPS exposure leads to increase in lateral ventricle size; effects were graded with the example demonstrating the most severe effects shown here. Panels A–C: Rostral to caudal section of air exposed males at PND 14 with lateral ventricle (LV) becoming visible indicted by arrowhead in Panel C. Panels D–E matched rostral to caudal sections of CAPS-treated males at PND14. Note: LV and CC damage apparent rostrally; Arrowheads in Panel D shows bridge across ventricle (fusion) and coarctation in LV in Panel E. Magnification 2×; CAPS = concentrated ambient ultrafine particles; PND = postnatal day; FCtx = frontal cortex; Cpu = caudate putamen. $n = 4$–5/group.

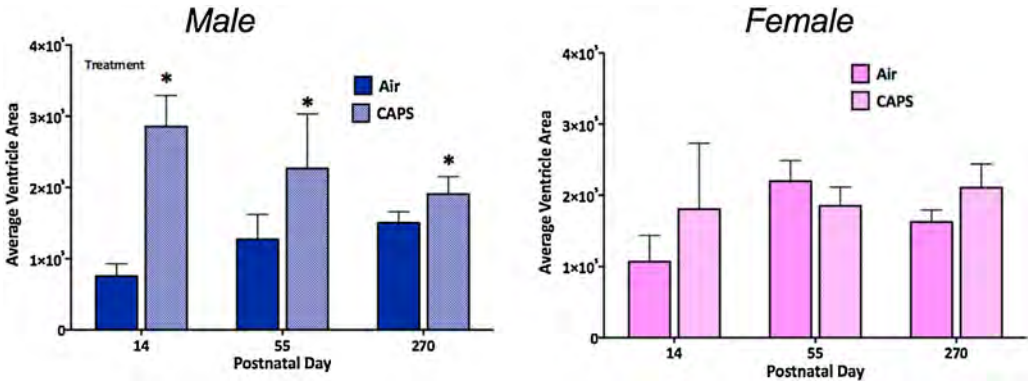

Fig. 3. CAPS exposure leads to male specific increased ventricular size. Lateral ventricle area (group mean ± S.E) of males (left panel) and females (right panel) treated with air or postnatal CAPS were measured at three time points: PND 14 (defined 24 h post exposure), PND 55 and PND 270; n = 4–6/group, average of at least 3 sections/brain. CAPS = concentrated ambient ultrafine particles; PND = postnatal day. Male data modified from (Allen et al., 2014a) and female data unpublished.

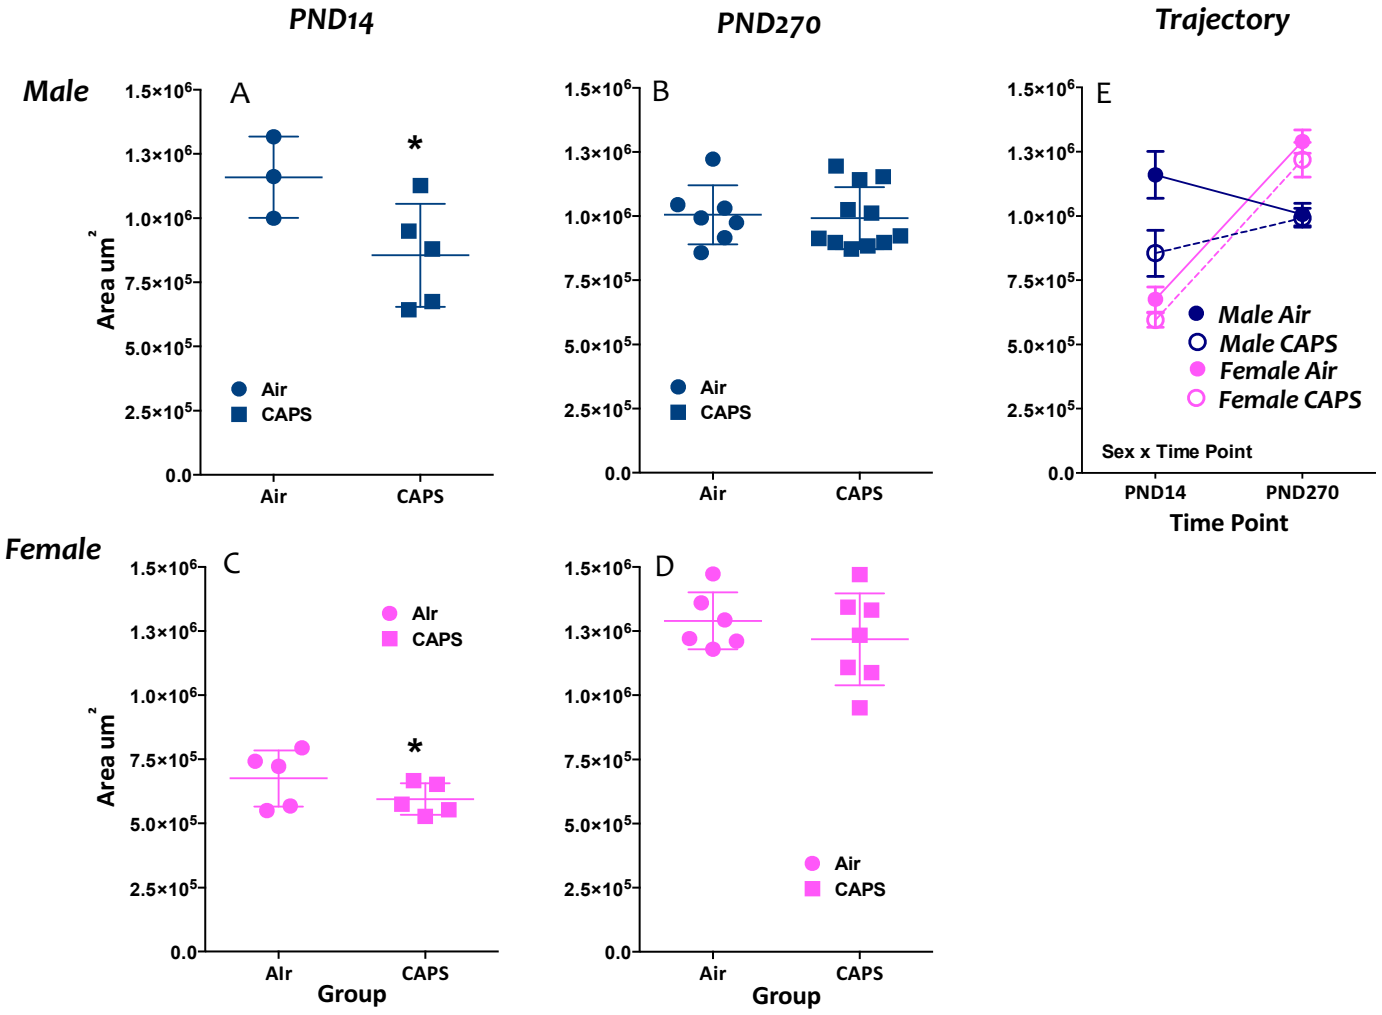

Fig. 4. CAPS treatment reduces size of CC in both sexes at PND14 with a trend towards greater magnitude effects in males. Panels A–D: CC size (μm^2) of individual male and female mice following air of postnatal CAPS treatment as measured at PND14 and PND270. Each data point represents an individual value. Sample sizes of 3–5 for PND14 and 7–11 for PND270. Panel E. Group mean ± S.E. size of CC across time points for male and females in treatment groups as indicated. CAPS = concentrated ambient ultrafine particles; PND = postnatal day; CC = corpus callosum.

delayed maturation to the adult pattern in females (Kim and Juraska, 1997).

At PND14, both males and females exhibited statistically significant CAPS-induced reductions in CC size (Fig. 4A and C), whereas no significant differences were found at PND270 (Fig. 4B and D). While CAPS-treated males showed a 30% size reduction compared to 10% in CAPS-treated females at PND14 relative to Air controls (Fig. 4A and C), statistical analysis of PND14 data confirmed only an effect of treatment ($F(1,14) = 8.1$, $p = 0.013$), but not a treatment by sex interaction that would statistically

confirm greater magnitude effects in males. However, as can be seen from the plotted individual data, differences among males at PND14 included a broader decrement with some overlap with Air controls, while evidence for female effects based on individual data were less biologically compelling. As can be observed in Fig. 4E, there appears to be no disruption of the trajectory of CC size in females, whereas an initial blunting is clear in males.

3.2.3. CC Myelination

The potential for altered myelination patterns was examined using MBP staining at three different sites along the CC, i.e., the truncus, the medial external capsule (MEC) and the lateral external capsule (LEC). At PND14 (Fig. 5A and B), marked reductions of approximately 35% in MBP staining within the CC were seen in males at the truncus that also extended to the medial external capsule (approximately 15%), whereas no significant differences in MBP staining area were seen in females at any point along the CC (overall ANOVA: treatment by sex by region, $F(2,28) = 3.39$, $p = 0.048$; post hoc p values for male PND14: site by treatment, $p = 0.018$; truncus, $p = 0.005$; medial external capsule, $p = 0028$). At PND270 (Fig. 5C and D), no statistically significant treatment related effects were found in either sex despite a visual trend towards hypomyelination in CAPS-treated females.

Fig. 5E–G present time-course trajectory changes in myelination for the truncus, medial external capsule and lateral external capsule, respectively. Consistent with the early sex-specific hypomyelination in males, significant treatment by sex × time point interactions were found for truncus and medial external capsule ($F(1,42) = 12.73$, $p = 0.0009$ and $F(1,42) = 6.62$, $p = 0.0137$, respectively). No CAPS-related changes in trajectory were found in the lateral external capsule, but, consistent with observations in truncus and medial external capsule, increases in area myelination occurred between PND14 and PND270.

In contrast to the CC, striatal myelination levels of females, while significantly higher than those of males at both time points (Fig. 6A and B) and also when considered across time (Fig. 6C, overall ANOVA: sex by time point, $F(1,40) = 4.19$, $p = 0.047$), showed no effects of CAPS in either sex. Levels of MBP staining in fontal cortex were generally quite low (Fig. 7A and B), although increasing between PND14 and PND270 (Fig. 7C), but did not differ by sex or CAPS treatment.

Some of these changes have also been reported to occur in ASD, including reductions in area and myelination of the corpus callosum (CC), the largest white matter tract in the brain (Melillo and Leisman, 2009; Barnea-Goraly et al., 2004) and a tract that is critical to inter-hemispheric communication/integration for sensory, motor and higher cognitive functions (Yates and Juraska, 2007). The consequences of such hypomyelination and reduced CC include under-connectivity of the two hemispheres, and increased localized connectivity. Both correlate with social and language deficits and altered hand preference/usage in ASD (Floris et al., 2013; Forrester et al., 2014; Geschwind and Levitt, 2007; Kana et al., 2011; Wass, 2011), an inter-hemispherically-based behavior. The particular thinning of the genu of the CC in ASD is notable, given its importance to frontal cortical connectivity, and it has been seen in conjunction with increased brain size and complexity of

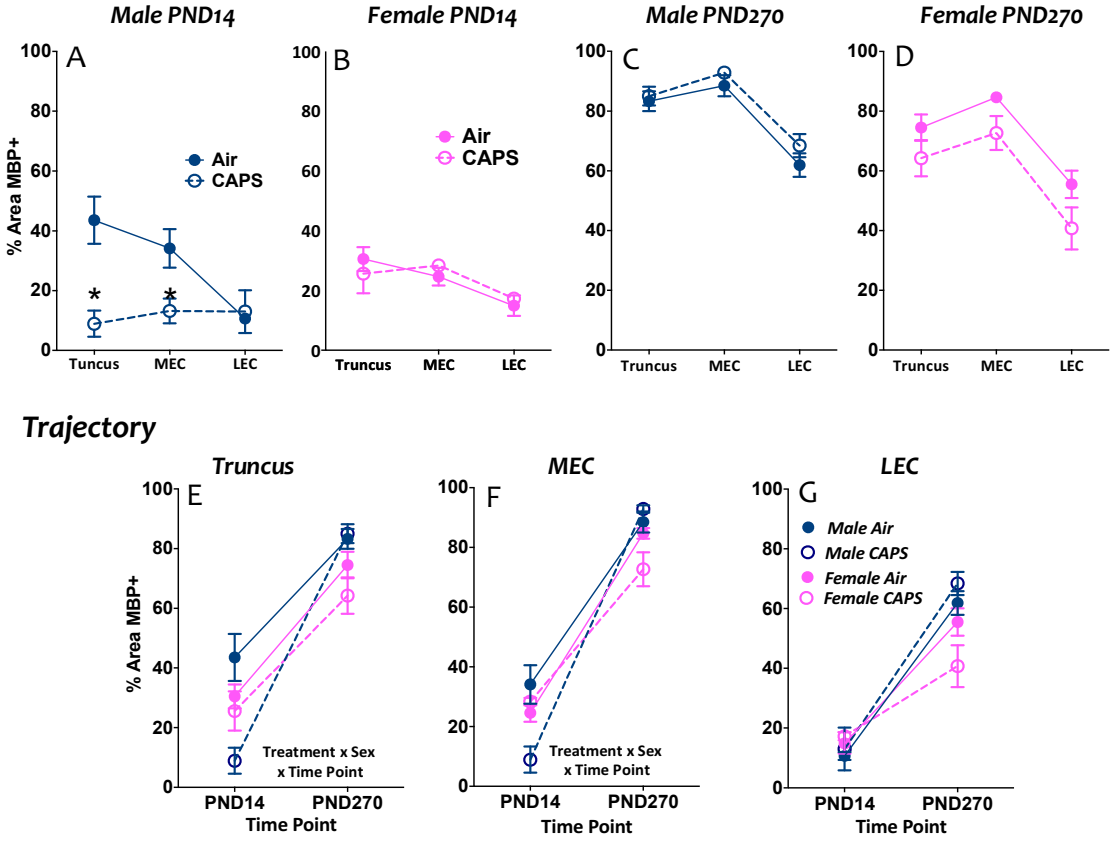

Fig. 5. CAPS treatment induces male specific CC hypomyelination at PND14. Panels A–D. Fluorescent intensity of myelin basic protein labeling expressed as percent of total CC area at PND14 (Panels A,B) and PND270 (Panels C and D) for male and female air vs. postnatal CAPS-treated mice as measured at 3 different sites along the CC: truncus, medial external capsule and lateral external capsule for treatment groups as indicated. Shown is group mean ± S.E. Panels E–G. Relative area of MBP labeling across time points for male and females in treatment groups as indicated for truncus, medial external capsule (MEC) and lateral external capsule (LEC), respectively. Treatment × sex × time point indicates significant 3-way interaction in overall ANOVAs. Sample sizes of 3–5 for PND14 and 4–11 for PND270. Shown is group mean ± S.E. CAPS = concentrated ambient ultrafine particles; PND = postnatal day; CC = corpus callosum.

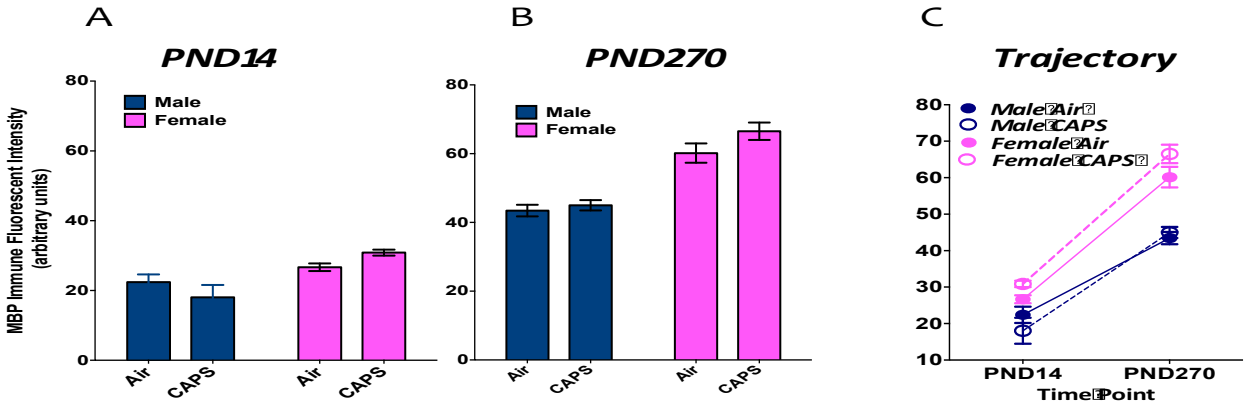

Fig. 6. CAPS exposure does not alter striatal myelination in either sex. Panels A–B: fluorescent intensity of myelin basic protein labeling expressed as arbitrary units in striatum at PND14 and PND270, respectively, for male and female air vs. postnatal CAPS-treated mice. Panel C: trajectory of density of myelin basic protein staining between PND14 and PND270 for males and females for indicated treatment groups. Sample sizes of 3–5 for PND14 and 4–11 for PND270. Shown is group mean ± S.E. CAPS = concentrated ambient ultrafine particles; PND = postnatal day.

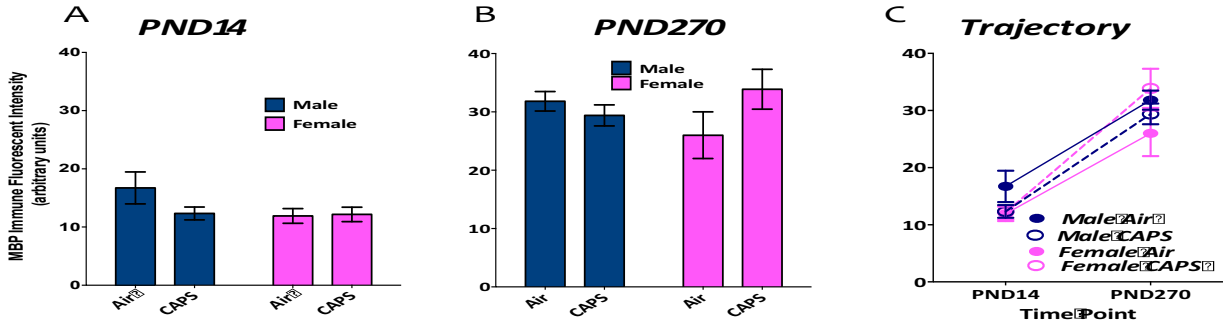

Fig. 7. CAPS treatment does not alter frontal cortex myelination in either sex. Panels A–B: density of myelin basic protein staining (μm^2) in frontal cortex at PND14 and PND270, respectively, for male and female air vs. postnatal CAPS-treated mice. Panel C: trajectory of density of myelin basic protein staining between PND14 and PND270 for males and females for indicated treatment groups. Sample sizes of 3–5 for PND14 and 4–11 for PND270. Data are group mean ± S.E. CAPS = concentrated ambient ultrafine particles; PND = postnatal day.

gyrification (Vidal et al., 2006). Despite some inconsistencies in profiles of white matter tract alterations in ASD (Koldewyn et al., 2014), diminished CC size has been a salient manifestation (Casanova and Pickett, 2013).

The observed VM we identified in CAPS exposure has also been reported in ASD and while this is not a prototypical pathology in ASD, it is a clinical indicator of white matter damage, and often accompanies CC disruption in ASD, likely reflecting an expansion of the ventricles to fill available space (Leviton and Gilles, 1996) due to delayed development and/or cell loss. In a low for birth weight cohort, ventricular enlargement in the first week of life was associated with a 7-fold increase in ASD diagnosis at 16 and 21 years of age (Movsas et al., 2013), and children with VM are found to be more likely to develop ASD (Piven et al., 1995).

3.3. Postnatal CAPS persistently elevated glutamate levels and resulted in male-specific excitatory–inhibitory imbalance, a pathology that is mirrored in ASD (Page et al., 2006)

CAPS increased total levels of frontal cortex glutamate, glutamine and GABA levels in both sexes at various times following postnatal exposures, as we have previously reported (Allen et al., 2014a,b,c). In males, but not females, glutamate levels in hippocampus were also elevated, suggesting potential for greater CAPS-associated excitotoxicity. Indeed, calculated as [Glu]/[GABA] ratios, only males showed significant hippocampal excitatory/inhibitory imbalance as shown for PND14 and PND60 (Fig. 8), as GABA increases were less pronounced than those of glutamate in males. These findings are consistent with the male specificity of

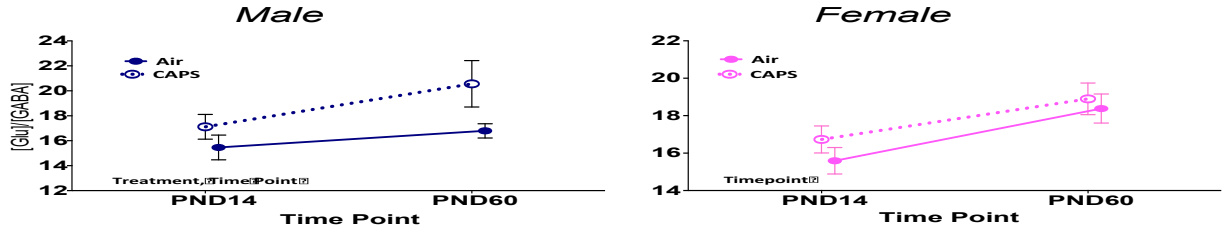

Fig. 8. CAPS produced a male specific frontal cortex excitatory/inhibitory imbalance. Glutamate/GABA ratios based on levels of frontal cortex at PND14 and PND60 as based on extracellular glutamate, glutamine and GABA in air vs. postnatal CAPS treated males (left panel) and female (right panel) mice. CAPS = concentrated ambient ultrafine particles; PND = postnatal day; treatment = main effect of CAPS in statistical analysis; timepoint = main effect of time point in statistical analysis, n = 9–12/group. Data modified from (Allen et al., 2014a) and (Allen et al., 2014b). Shown are group means ± S.E.

microglial activation (Fig. 1) and its potential to produce glutamate release (Murugan et al., 2013; Takeuchi et al., 2005) seen in ASD.

It has been reported that children and adults with ASD show altered glutamatergic balance, both in the periphery and CNS (Naushad et al., 2013; Kuwabara et al., 2013; Horder et al., 2013; Bejjani et al., 2012; Shimmura et al., 2011; Choudhury et al., 2012), which can correlate with altered social functioning (Horder et al., 2013). Single nucleotide polymorphisms in glutamate transporter genes (Jacob et al., 2011), and astrocyte specific dysfunctions that affect glutamate metabolism (Kondapalli et al., 2013), have been found in genetic variants in ASD. These variants affect genes in the neurexin-neuroligin gene superfamily that are important to regulation of glutamatergic synapse formation (Chih et al., 2005). Collectively these finding contribute to the 'hyperglutamate theory' of ASD (Jacob et al., 2011). As noted above, microglial activation/inflammation could trigger glutamate release (Murugan et al., 2013; Takeuchi et al., 2005), and glutamate release further activate microglia (Biber et al., 2007).

3.4. Postnatal CAPS produces astrocytic activation in amygdala consistent with the aberrant amygdala theory of ASD (Baron-Cohen et al., 2000; Cahill et al., 2004; Ruigrok et al., 2014)

We have identified significant increases in the astrocyte specific marker GFAP in amygdala of CAPS-treated males at PND14 (Fig. 9). This adds yet another brain region impacted by UFPs that is considered key to aberrant behaviors involved in ASD (Baron-Cohen et al., 2000). Data from females and later time points are not yet examined, so the extent to which this effect is sex-differential is not yet known.

ASD brains also show altered amygdala volume, marked by early enlargement and normal or reduced volumes in adulthood, that can be linked to social abnormalities in ASD (Schumann et al., 2004, 2009). A recent report cited fewer amygdala neurons in some males diagnosed with ASD (Morgan et al., 2010).

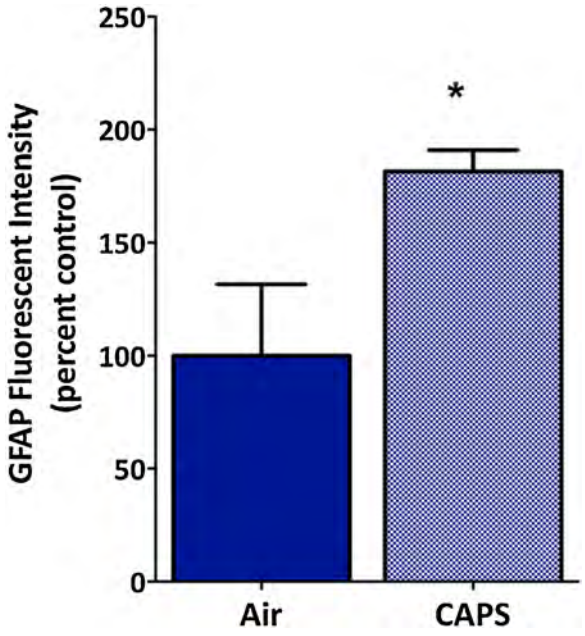

Fig. 9. CAPS exposure increased GFAP labeling in amygdala. Fluorescent intensity of GFAP labeling in amygdala in male mice exposed to postnatal CAPS at PND14 and normalized to air exposed controls. $n = 5$/gp. Shown is group mean ± S.E. CAPS = concentrated ambient ultrafine particles; PND = postnatal day; GFAP = glial fibrillary acidic protein.

3.5. Postnatal CAPS is associated with impulsive-like behavior that has also been reported in ASD

Where diagnosis is predicated on primary behavioral characteristics that include social deficits, impaired communication, and repetition/perseveration (Lai et al., 2014). Executive functions including set shifting can also be impaired in ASD and are frequent co-morbid features of the disorder (Vidal et al., 2006; Troyb et al., 2014; Ravizza et al., 2013; Rosenthal et al., 2013; Christ et al., 2011; Lemon et al., 2011; Scott-Van Zeeland et al., 2010).

The unexpected observations of disrupted CC white matter development, VM and excitatory/inhibitory imbalance in response to CAPS treatment were found only after our completion of behavioral testing in our studies, and therefore explicit testing for these primary ASD behavioral domains has not yet been completed, nor were all behavioral assays that have been implemented carried out in both sexes. Consequently, the full extent to which postnatal CAPS reproduces ASD behavioral features and its sex-dependence is not yet fully delineated.

However, other behavioral dysfunctions associated with ASD have been found in response to CAPS treatment, including perseverative/impulsive behavior in CAPS males (females not yet tested) on a Fixed Ratio waiting for reward paradigm that required 25 lever press responses in an operant chamber to initiate a waiting component during which free reward deliveries occurred. However, the time between each successive free reward delivery doubled during the wait component, thus requiring increasingly longer wait times, and any lever press response during the waiting component re-set the 25 response requirement to re-start the wait component. Postnatal CAPS markedly decreased mean waiting time and increased numbers of fixed ratio resets in males, despite the added cost in terms of numbers of responses required for each reward delivery (Allen et al., 2013). Fig. 10 presents cumulative records of an individual subject from each treatment group depicting this perseverative/impulsive behavior, behaviors consistent with ASD-like repetition and impulsivity.

Sex-dependent deficits in executive-type behavioral domains were also found after CAPS, including alterations in learning, reversal learning, and memory even out to 14 mos (final time point of behavioral observations). Both sexes showed novel object recognition deficits (considered to reflect short term memory) (Allen et al., 2014b) and impairments in repeated learning (in preparation; data not shown), i.e., ability to learn new 3-response chains for reward delivery in each successive behavioral test session, but no deficits in performing a constant already learned 3 response chains, consistent with a selective learning deficit.

4. Discussion

Postnatal exposures of mice to ambient UFP appear to reproduce many features consistent with characteristics of ASD, including inflammation/microglial activation (Fig. 1), reduced CC size (Fig. 4), aberrant white matter development and/or structural integrity (Figs. 2–5), hypomyelination (Fig. 5) and VM (Figs. 2–3), an altered ratio of glutamate and GABA, consistent with excitatory/inhibitory imbalance (Fig. 8), and alterations in GFAP expression in the amygdala (Fig. 9), many of which were either male-specific or of greater magnitude in males. While we are still in the process of completing behavioral tests that define ASD-like behavior in animal models, we found deficits in learning, short-term memory (not shown) and, in males, repetitive and impulsive-like behaviors (Fig. 10), which are part of the primary diagnostic domain of ASD.

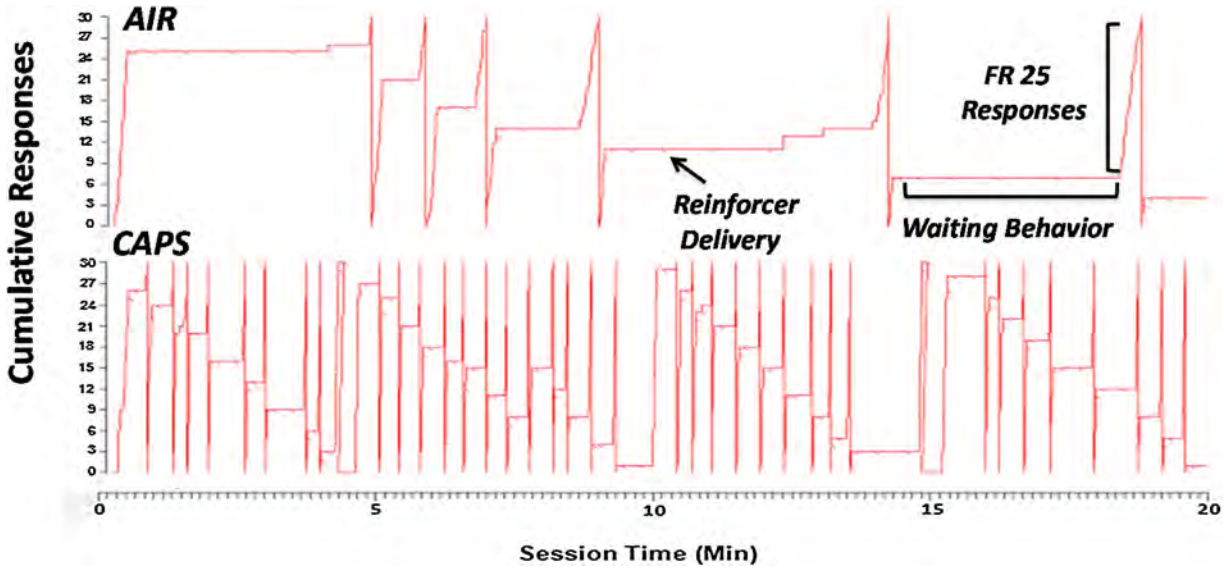

Fig. 10. Cumulative records of individual male from indicated treatment groups on the fixed ratio (FR) wait schedule. *Y* axis response counter resets to baseline after each 30 responses; pips (backslashes) = reward delivery, horizontal lines = periods of waiting, vertical lines = FR responding. Modified from (Allen et al., 2013).

4.1. White matter damage

New analyses presented here reveal UFP-induced white matter alterations at PND14 selectively in commissural tracts (CC), with effects that were of significantly greater magnitude in males, consistent with our previous observation of male-specific and persistent microglial activation and VM (Allen et al., 2014a,b). These changes included both a significantly reduced CC size, as well as male-specific hypomyelination of CC at PND 14, with marked reductions particularly in the truncus and the medial, as opposed to the lateral external capsule. CC size ultimately reached control levels later in life following postnatal CAPS in males, whereas small but non-significant reductions in myelination were suggestive in females at PND270, findings that could indicate delayed neurotoxicity in this sex and perhaps repair in males. In contrast, no changes were seen in white matter in either striatum or in frontal cortex in either sex.

The reduction of CC size and region-specific hypomyelination coupled with our prior observations of persistent microglial activation and VM (Allen et al., 2014a) is markedly similar to the clinical conditions of diffuse periventricular leukomalacia or white matter injury of prematurity/neonatal white matter damage (Leviton and Gilles, 1996; Rezaie and Dean, 2002) that can be produced by fetal inflammatory or hypoxic-ischemic injury. VM is a clinical indicator of disrupted white matter development (Allen et al., 2014a,b) and can be accompanied by significant cognitive deficits (Leviton and Gilles, 1996). Based on its well-known inflammatory properties (Kelly and Fussell, 2015), UFP exposures would be expected to activate brain microglia, resulting in the release of proinflammatory cytokines (Baburamani et al., 2014; Harry and Kraft, 2012; Chew et al., 2013) that could lead to hypomyelination via toxicity to oligodendrocytes, the myelinating cells of the brain (El Waly et al., 2014). Indeed, particular vulnerability of premyelinating olidgodendrocytes to such consequences of microglial activation has been described (Liu et al., 2013; Volpe et al., 2011). Such scenarios are considered the underlying basis of disrupted white matter development associated with prematurity (Rezaie and Dean, 2002).

Our collective findings raise several important questions. For example, what underlies the preferential male vulnerability to the early reduction in CC size and hypomyelination? One hypothesis relates to the greater number of colonizing activated microglia in male brain at the time of CAPS exposure (Schwarz et al., 2012). Neuro- and gliogenesis, which derive from germinal ventricular and subventricular zones next to the ventricle walls, occurs at peak levels during the postnatal period when CAPS exposures occurred (Bandeira et al., 2009), and continues at a constant level into young adulthood (Tabata et al., 2012; Tramontin et al., 2003), with activated microglia actually required for neuro- and oligodendrogenesis through the release of cytokines (potentially in combinations), including IL-1β and IL-6 (Shigemoto-Mogami et al., 2014). However, the greater number of activated microglia, despite its requirement for neuro- and gliogenesis to proceed, could also render male brain microglia more vulnerable to dysfunction or even cell death in response to an ongoing inflammatory insult. Females exhibit increased numbers and more activated microglia than males only at a later postnatal age (PND30) (Schwarz et al., 2012), and thus CAPS exposures in these studies may have preceded the period of female vulnerability.

Other questions raised by our data are what underlies the preferential vulnerability of the truncus of the CC to CAPS-induced hypomyelination, and, what accounts for the lack of vulnerability of striatal and frontal cortex (non-commissural) white matter myelination? One potential contributor to these dichotomous effects could be regional differences in timing of myelination in early development relative to the CAPS exposure period. Interestingly, as in humans (Bird et al., 1989), myelination in mouse brain occurs earliest in the caudal part of the CC (PND14) and only later in the anterior segments, i.e., truncus and genu, e.g., between PND21-28 (Vincze et al., 2008). Myelination of regions such as striatum and cortex occurs even later, with studies showing myelination levels of only 1% in frontal cortex at PND21, up to about 15% at PND90, and up to approximately 70% at PND 180. At PND21, myelination of striatum is only about 5% of the area, and increases to about 28% by PND90 (Mengler et al., 2014).

Thus, it may be that the absence of white matter myelination changes in striatum and frontal cortex reflects the fact that these processes are occurring at a sufficiently later time relative to CAPS exposures and thus are spared, and/or that any ongoing inflammation levels have subsided in that period. With respect to the vulnerability of the truncus of the CC, its primary myelination occurs 1–2 weeks post CAPS exposures, while more caudal parts of CC are undergoing myelination during the period of CAPS exposure itself. This also means that the entirety of CAPS

exposure (cumulative exposure) preceded the period associated with truncus (and genu) myelination, whereas a lesser 'dose' of exposure occurred during myelination of more caudal regions. Thus, there may have been insufficient inflammation during the earlier periods of myelination, whereas a more protracted/higher level of inflammation period ended only days prior to myelination of the truncus/genu. An additional consideration is that perinatal white matter injury can be accompanied by neuronal damage (Wahlsten, 1984; Leviton and Gressens, 2007), including cortical subplate neurons that are critical to formation of axons for the CC, raising the possibility that these neurons were either dysfunctional or dead the thus the infrastructure for myelination never developed, a hypothesis that has yet to be examined.

Hypomyelination at the truncus, i.e., just posterior to the genu, is of particular significance given that these fibers connect motor and prefrontal cortical areas, respectively, and preserve hemispheric connectivity (Pandya and Seltzer, 1986; Barbas and Pandya, 1984; Paul et al., 2007). White matter alterations in these regions have been associated in adolescents with a history of preterm birth, e.g., with cognitive outcomes (Narberhaus et al., 2008) as well as with deficits in social communication (Ewing-Cobbs et al., 2012). In the context of cognitive outcomes, it is notable that air pollution is also associated with prematurity and reductions in birth weight (Shah and Balkhair, 2011; Stieb et al., 2012).

4.2. Air pollution as a broader risk factor: ASD shares features with other neurodevelopmental disorders

Different components of the observed profile of CAPS-induced neuropathology are actually consistent with multiple neurodevelopmental disorders, including ASD (Melillo and Leisman, 2009; Aoki et al., 2013; Keller et al., 2007; Barnea-Goraly et al., 2004), schizophrenia (Lener et al., 2015), and attention deficit disorder (Langevin et al., 2014; Chaim et al., 2014; Newbury and Rosen, 2012; Paul, 2011; Gilliam et al., 2011; Qiu et al., 2011; Schnoebelen et al., 2010; Cao et al., 2010) among others, all of which also show a higher prevalence in males, consistent with the male dominance of outcomes observed here. ASD and schizophrenia, for example, particularly childhood onset schizophrenia, are frequently considered components of a shared spectrum (Cheung et al., 2010; King and Lord, 2011; Meyer et al., 2011; Rapoport et al., 2009). Prior to 1971 these disorders were generally lumped together as 'childhood psychosis', with ASD considered an early manifestation of schizophrenia. They can occur as co-morbidities, and behaviorally, both include deficits in social interactions, cognition, executive functions, emotional processing and sensorimotor gating. Both can involve auditory and visual hallucinations (Meyer et al., 2011; Barneveld et al., 2011), abnormalities of serotonergic, dopaminergic and glutamatergic systems (Brown et al., 2013; Shimmura et al., 2013; Sodhi and Sanders-Bush., 2004) and shared genetic causes (de Lacy and King, 2013; Smoller et al., 2013). Schizophrenia and ASD also share neuropathological features, including VM (Palmen et al., 2005; Sanfilipo et al., 2000; Shen et al., 2013), a clinical indicator of white matter alterations that are crucial to brain interhemispheric connectivity.

Adverse pregnancy outcomes, specifically preterm birth and reduced birth weight are often associated with brain white matter alterations (Elitt and Rosenberg, 2014; Volpe, 2003), as seen in conditions such as periventricular leukomalacia (Back, 2006), that have been linked to inflammatory mechanisms (Melhem et al., 2000; Perlman, 1998; Wang et al., 2013), and can lead to cognitive impairments. In up to 50% of extremely and very preterm infants, alterations in brain white matter constitute the most important basis of axonal/neuronal damage associated with adverse neurocognitive and motor development (Back and Rosenberg, 2014). As noted above, links between prematurity and reduced birth weight with air pollution are increasingly reported (Shah and Balkhair, 2011; Stieb et al., 2012). Alterations in brain white matter are also observed in attention deficit hyperactivity disorder (Gilliam et al., 2011). Disconnectivity, i.e., functional and/or anatomical damage to white matter axons in communicating pathways found in ASD and schizophrenia (Geschwind and Levitt, 2007; Kana et al., 2011; Wass, 2011; Guo et al., 2013), is critical to language, social behavior and some cognitive functions. VM associated with such deficits persists after birth (Gilmore et al., 2001) and is more prevalent in males (Gilmore et al., 1998). Prenatal VM is predictive of time to first-episode psychosis, and schizophrenia diagnosis (Sanfilipo et al., 2000; Gilmore et al., 1998, 2008; Fannon et al., 2000; Kyriakopoulou et al., 2013).

Animal models yielding a similar neuropathological profile to that produced by CAPS treatment can result from exposures to hypoxia, ischemia, maternal-fetal infection and lipopolysaccharide (endotoxin) administration (Yates and Juraska, 2007). Frequently observed in such pathology is an early necrosis in the subventricular zone adjacent to the lateral ventricle with depletion of stem cells, followed by later proliferation, as also observed in conditions such as periventricular leukomalacia (Back, 2006). Numerous studies now demonstrate the role of reactive microglia, with a particular vulnerability of premyelinating oligodendroglia, to such insults (Leviton and Gilles, 1996; Back and Rosenberg, 2014).

5. Conclusions

The findings reported here have two major implications: first, the data highlight the human 3rd trimester equivalent (Clancy et al., 2007a; Rice and Barone, 2000) as a period of potential vulnerability to neurodevelopmental toxicity to ambient UFP, particularly in males, adding to a growing body of evidence that brain is a target of air pollution, and point to the possibility that UFP exposure during periods of rapid neuro- and gliogenesis may be a risk factor for neurodevelopmental disorders. The most prominent period of myelination in the mouse begins at approximately PND10 (Vincze et al., 2008; Bockhorst et al., 2008; Sturrock, 1980) and thus is encompassed by our CAPS exposures. One cited limitation of rodent models of inhaled air pollution has been that rodents, unlike humans, are obligate nose-breathers and thus dosing to mouse results in higher exposures relative to humans. However, this may be a minimal or negligent concern according to a recent study based on computational modeling using an anatomically accurate model of the human nasal cavity that found that the olfactory dose per unit surface area is actually estimated to be higher in humans for 1–7 nm particles based on the larger inhalation rates of humans (Garcia et al., 2015). The latter is of particular note as emphasized in a recent editorial (Pedata et al., 2015), given the presence in fly ash and car exhaust of a significant fraction of particles below 10 nm, often overlooked because of measurement difficulty (Ronkko et al., 2007).

Second, ASD phenotypic expression and severity shows broad variability. If a risk factor for ASD, the variability of air pollution levels and composition across seasons/climate/geography could assist in contributing to the heterogeneity of the phenotype, which could be further compounded by the developmental timing of the exposure. Current thinking posits that the multifactorial genetic and environmental risks for ASD superimposed on different periods of brain development, could ostensibly underlie this variability of the phenotype. Air pollution, as one such risk factor, could pose a greater threat in more highly polluted regions and/or in areas where it includes more toxic elements. Inconsistencies across ASD studies could in part reflect the convergence of different sets of risk factors occurring in geographically different

cohorts and significant differences in UFP exposures could also occur within even cohorts.

Traffic-Related Air Pollution, Particulate Matter, and Autism

Heather E. Volk, PhD, MPH; Fred Lurmann; Bryan Penfold; Irva Hertz-Picciotto, PhD; Rob McConnell, MD

Context: Autism is a heterogeneous disorder with genetic and environmental factors likely contributing to its origins. Examination of hazardous pollutants has suggested the importance of air toxics in the etiology of autism, yet little research has examined its association with local levels of air pollution using residence-specific exposure assignments.

Objective: To examine the relationship between traffic-related air pollution, air quality, and autism.

Design: This population-based case-control study includes data obtained from children with autism and control children with typical development who were enrolled in the Childhood Autism Risks from Genetics and the Environment study in California. The mother's address from the birth certificate and addresses reported from a residential history questionnaire were used to estimate exposure for each trimester of pregnancy and first year of life. Traffic-related air pollution was assigned to each location using a line-source air-quality dispersion model. Regional air pollutant measures were based on the Environmental Protection Agency's Air Quality System data. Logistic regression models compared estimated and measured pollutant levels for children with autism and for control children with typical development.

Setting: Case-control study from California.

Participants: A total of 279 children with autism and a total of 245 control children with typical development.

Main Outcome Measures: Crude and multivariable adjusted odds ratios (AORs) for autism.

Results: Children with autism were more likely to live at residences that had the highest quartile of exposure to traffic-related air pollution, during gestation (AOR, 1.98 [95% CI, 1.20-3.31]) and during the first year of life (AOR, 3.10 [95% CI, 1.76-5.57]), compared with control children. Regional exposure measures of nitrogen dioxide and particulate matter less than 2.5 and 10 μm in diameter ($PM_{2.5}$ and PM_{10}) were also associated with autism during gestation (exposure to nitrogen dioxide: AOR, 1.81 [95% CI, 1.37-3.09]; exposure to $PM_{2.5}$: AOR, 2.08 [95% CI, 1.93-2.25]; exposure to PM_{10}: AOR, 2.17 [95% CI, 1.49-3.16) and during the first year of life (exposure to nitrogen dioxide: AOR, 2.06 [95% CI, 1.37-3.09]; exposure to $PM_{2.5}$: AOR, 2.12 [95% CI, 1.45-3.10]; exposure to PM_{10}: AOR, 2.14 [95% CI, 1.46-3.12]). All regional pollutant estimates were scaled to twice the standard deviation of the distribution for all pregnancy estimates.

Conclusions: Exposure to traffic-related air pollution, nitrogen dioxide, $PM_{2.5}$, and PM_{10} during pregnancy and during the first year of life was associated with autism. Further epidemiological and toxicological examinations of likely biological pathways will help determine whether these associations are causal.

AUTISM SPECTRUM DISORDERS are a group of developmental disorders commonly characterized by problems in communication, social interaction, and repetitive behaviors or restricted interests.[1] Although the severity of impairment for the autism spectrum disorders varies across the spectrum (full syndrome autism being the most severe), the incidence rate of all autism spectrum disorders is now reported to be as high as 1 in 110 children.[2] Emerging evidence suggests that environment plays a role in autism, yet at this stage, only limited information is available as to what exposures are relevant, their mechanisms of action, the stages of development in which they act, and the development of effective preventive measures.

For editorial comment see page 9

Recently, air pollution has been examined as a potential risk factor for autism.

Table 1. Spearman Correlations of Traffic-Related Air Pollution (TRP) and Regional Pollutants for 524 Children[a]

First Year of Life Estimates	All Pregnancy Estimates				
	TRP	$PM_{2.5}$	PM_{10}	Ozone	Nitrogen Dioxide
TRP	0.92[b]	0.36[c]	0.33[c]	–0.36[c]	0.60[c]
$PM_{2.5}$	0.25[d]	0.67[b]	0.77[c]	–0.11[c]	0.63[c]
PM_{10}	0.27[d]	0.84[d]	0.82[b]	0.13[c]	0.66[c]
Ozone	–0.31[d]	0.26[d]	0.27[d]	0.74[b]	–0.29[c]
Nitrogen dioxide	0.58[d]	0.60[d]	0.64[d]	–0.19[d]	0.89[b]

Abbreviations: $PM_{2.5}$, particulate matter less than 2.5 μm in aerodynamic diameter; PM_{10}, particulate matter less than 10 μm in aerodynamic diameter.
[a] All correlation measures were statistically significant ($P < .05$).
[b] Correlations of the same pollutant across time periods.
[c] Correlations across pollutants within pregnancy.
[d] Correlations across pollutants within the first year of life.

Using the Environmental Protection Agency's dispersion-model estimates of ambient concentrations of hazardous air pollutants, Windham and colleagues[3] identified an increased risk of autism based on exposure to diesel exhaust particles, metals (mercury, cadmium, and nickel), and chlorinated solvents in Northern California census tracts. Additional research using dispersion-model estimates of hazardous air pollutants also reported associations between autism and air toxics at the birth residences of children from North Carolina and West Virginia.[4] These epidemiologic findings on autism are supported by additional research[5,6] describing other physical and developmental effects of air pollution due to prenatal and early life exposure. For example, high levels of air pollutants have been associated with poor birth outcomes, immunologic changes, and decreased cognitive abilities.[5,6]

Recently, we reported an association between the risk of autism and an early life residence within 309 m of a freeway in the Childhood Autism Risks from Genetics and the Environment (CHARGE) study.[7] The near-source traffic-related air pollutant mixture has a large spatial variation, returning to near-background daytime levels beyond this distance.[8,9] Herein, we report associations of autism with estimates of exposure to the mixture of traffic-related air pollution and with regional measures of nitrogen dioxide, particulate matter less than 2.5 μm in aerodynamic diameter ($PM_{2.5}$), and particulate matter less than 10 μm in aerodynamic diameter (PM_{10}) in the CHARGE sample.

METHODS

The CHARGE study is a population-based case-control study of preschool children. The study design is described in detail elsewhere.[10] In brief, the participants in the CHARGE study were between the ages of 24 and 60 months at the time of recruitment, lived with at least one English- or Spanish-speaking biologic parent, were born in California, and lived in one of the study catchment areas. Recruitment was facilitated by the California Department of Developmental Services, the regional centers with which they contract to coordinate services for persons with developmental disabilities, and referrals from the MIND (Medical Investigation of Neurodevelopmental Disorders) Institute clinic at the University of California, Davis, and from other research studies. Population-based control children were recruited from the sampling frame of birth files from the state of California and were frequency matched by sex, age, and broad geographic area to the children with autism.

Each participating family was evaluated. Children with a previous diagnosis of autism were evaluated using the Autism Diagnostic Observation Schedules, and parents were administered the Autism Diagnostic Interview–Revised.[11,12] Children who received a diagnosis of developmental delay and control children from the general population were given the Social Communication Questionnaire to screen for the presence of autistic features.[13] If the Social Communication Questionnaire score was 15 or greater, the child was then evaluated using the Autism Diagnostic Observation Schedules, and the parent was administered the Autism Diagnostic Interview–Revised. In our study, autism cases were children with a diagnosis of full syndrome autism from both the Autism Diagnostic Observation Schedules and the Autism Diagnostic Interview–Revised. All children were also assessed using the Mullen Scales of Early Learning and the Vineland Adaptive Behavior Scales to collect information on motor skills, language, socialization, and daily living skills.[14,15] Controls were children from the general population who received a Social Communication Questionnaire score of less than 15 and who also showed no evidence of other types of delay (cognitive or adaptive).

Parents were interviewed to obtain, among other factors, demographic and medical information and residential histories. Race/ethnicity data were collected by self-report in categories defined by the US Census (**Table 1**). The residential data captured addresses and corresponding dates the mother and child lived at each location beginning 3 months before conception and extending to the most recent place of residence. Further details about the collection of clinical and exposure data have been previously reported.[10]

To obtain model-based estimates of exposure to traffic-related air pollution, we applied the CALINE4 line-source air-quality dispersion model.[16] The dispersion model was used to estimate average concentrations for the specific locations and time periods (trimesters of gestation and first year of life) for each participant. The principal model inputs are roadway geometry, link-based traffic volumes, period-specific meteorological conditions (wind speed and direction, atmospheric stability, and mixing heights), and vehicle emission rates. Detailed roadway geometry data and annual average daily traffic counts were obtained from Tele Atlas/Geographic Data Technology in 2005. These data represent an integration of state-, county-, and city-level traffic counts collected between 1995 and 2000. Because our period of interest was from 1997 to 2008, the counts were scaled to represent individual years based on estimated growth in county average vehicle-miles-traveled data.[17] Traffic counts were assigned to roadways based on location and street names. Traffic volumes on roadways without count data (mostly

©2013 American Medical Association. All rights reserved.

Downloaded From: by a SCELC - University of Southern California User on 10/25/2017

small roads) were estimated based on median volumes for similar class roads in small geographic regions. Meteorological data from 56 local monitoring stations were matched to the dates and locations of interest. Vehicle fleet average emission factors were based on the California Air Resource Board's EMFAC2007 (version 2.3) model. Annual average emission factors were calculated by year (1997-2008) for travel on freeways (65 mph), state highways (50 mph), arterials (35 mph), and collector roads (30 mph) (to convert to kilometers, multiply by 1.6). We used the CALINE4 model to estimate locally varying ambient concentrations of nitrogen oxides contributed by freeways, nonfreeways, and all roads located within 5 km of each child's home. Previously, we have used the CALINE4 model to estimate concentrations of other traffic-related pollutants, including elemental carbon and carbon monoxide, and found that they were almost perfectly correlated (around 0.99) with estimates for nitrogen oxides. Thus, our model-based concentrations should be viewed as an indicator of the traffic-related pollutant mixture rather than of any pollutant specifically.

A second approach was to use the regional air quality data for the exposure assignments for $PM_{2.5}$, PM_{10}, ozone, and nitrogen dioxide. These were derived from the US Environmental Protection Agency's Air Quality System data (http://www.epa.gov/ttn/airs/airsaqs) supplemented by University of Southern California Children's Health Study data for 1997 though 2009.[18] The Children's Health Study continuous PM data were used for a given monitoring station when no Federal Reference/Equivalent Method data for PM were available from the Air Quality System. The monthly air quality data from monitoring stations located within 50 km of each residence were made available for spatial interpolation of ambient concentrations. The spatial interpolations were based on inverse distance–squared weighting of data from up to 4 of the closest stations located within 50 km of each participant's residence; however, if 1 or more stations were located within 5 km of a residence, then only data from the stations within 5 km were used for the interpolation. Because special studies have shown large offshore-to-onshore pollutant gradients along the Southern California coast, the interpolations were performed with pseudostations (or theoretical locations used for estimating pollution gradients from extant data when geography did not permit observed data) located approximately 20 to 40 km offshore that had background concentrations based on long-term measurements (1994-2003) at clean coastal locations (ie, Lompoc, California).

Periods and locations relevant to the modeled traffic exposure were identified based on dates and addresses recorded on the child's birth certificate and from the residential history questionnaire. The birth certificate addresses corresponded to the mother's residence at the time of the child's birth, whereas the residential history captures both the mother's residences during pregnancy (required for estimation of prenatal exposure) and the child's residences after birth through the time of study enrollment. We determined the conception date for each child using gestational age from ultrasonographic measurements or the date of last menstrual period, as determined from prenatal records. We used these locations and dates to estimate exposure for the child's first year of life, for the entire pregnancy period, and for each trimester of pregnancy. When more than 1 address fell into a time interval, we created a weighted average to reflect the exposure level of the participant across the time of interest, taking into account changes in residence. Traffic-related air pollution was determined based on the required inputs reflecting change in each address over the study period. For the regional pollutant measures, we assigned $PM_{2.5}$, PM_{10}, and nitrogen dioxide measurements based on average concentrations for the time period of interest. For ozone, we calculated the averages for the period of interest based on the average range of ozone measurements from 1000 to 1800 hours (reflecting the high 8-hour daytime). Based on these methods, we were able to assign traffic-related air pollutant estimates and regional pollutant measures for 524 mother-child pairs.

Spearman correlations were calculated pairwise between traffic-related air pollutant estimates and regional pollution measures for pregnancy and the first year of life to assess the independence of these exposure metrics. We used logistic regression to examine the association between exposure to traffic-related air pollution and the risk of autism. Models of autism risk as a function of traffic-related air pollutant exposure levels from all road types were fitted separately for each time period. Categories of exposure were formed based on quartiles of the traffic-related air pollutant distribution for all pregnancy estimates because this provided the most comprehensive data for each child. Levels of regional pollutants were examined as continuous variables, and effect estimates were scaled to twice the standard deviation of the distribution for all pregnancy estimates. When levels of correlation permitted, we examined both traffic-related air pollutants and regional pollutants in a single model. Pertinent covariates were included in each model to adjust for potential confounding due to sociodemographic and lifestyle characteristics. We included children's sex and ethnicity, maximum education level of the parents, mother's age, and whether the mother smoked during her pregnancy, as described previously.[7] To examine whether our findings were affected by participants living in an urban or rural area, we included population density, which was obtained from Environmental Systems Research Institute Inc 2008 estimates of people per square meter using ArcGIS software version 9.2. We used the US Census Bureau cutoff of 2500 people per square meter to categorize population density into urban vs rural areas and included this variable as a covariate in our analysis of the effects of air pollution from the first year of life because these residences were the most recently recorded.

We also fitted logistic additive models to evaluate the relationship between autism and traffic-related air pollution. These models used the smoothing spline with 3 degrees of freedom for continuous traffic-related air pollution and used the same adjustment variables as in the linear logistic models already described. Statistical tests were conducted using an α level of .05, and 95% CIs were used to measure precision. All analyses were conducted using the R package version 2.9.2 (http://www.r-project.org). The institutional review boards of the University of Southern California and the University of California, Davis, approved the research.

RESULTS

The children in our study were predominantly male (84%), and most were non-Hispanic white (50%) or Hispanic (30%). No differences were found between cases and controls for any demographic, socioeconomic, or lifestyle variables that we examined (eTable, http://www.jamapsych.com). Details regarding the exposure distributions are presented in the eFigure, A and B. The Spearman correlations calculated for the first year of life and the pregnancy time periods are presented in Table 1. During pregnancy and during the first year of life, traffic-related air pollution was moderately correlated with $PM_{2.5}$ and PM_{10}, highly correlated with nitrogen dioxide, but inversely correlated with ozone. Among the regional pollutant measures, $PM_{2.5}$ and PM_{10} were nearly perfectly correlated, and both were highly correlated with nitrogen dioxide. Correlations with ozone were low and often negative, demonstrating an inverse relationship. We also ex-

Adjusted[b]	2.10 (1.27-3.51)	0.91 (0.56-1.46)	1.17 (0.71-1.93)

[a] Quartile cut points correspond to traffic-related air pollution exposure levels of 31.8 ppb or greater (fourth quartile), 16.9 to 31.8 ppb (third quartile), and 9.7 to 16.9 ppb (second quartile), compared with 9.7 ppb or less (first quartile [reference group]).

[b] Model adjusted for male sex of child, child's ethnicity (Hispanic vs white; black/Asian/other vs white), maximum education of parents (parent with highest of 4 levels: college degree or higher vs some high school, high school degree, or some college education), maternal age (>35 years vs ≤35 years), and prenatal smoking (mother's self-report of ever vs never smoked while pregnant).

amined correlations of each pollutant across time periods, and high levels of correlation were identified.

EXPOSURE TO TRAFFIC-RELATED AIR POLLUTION

An increased risk of autism was associated with exposure to traffic-related air pollution during a child's first year of life. Children residing in homes with the highest levels of modeled traffic-related air pollution were 3 times as likely to have autism compared with children residing in homes with the lowest levels of exposure (**Table 2**). Exposure in the middle quartile groups (second and third quartiles) was not associated with an increased risk of autism. In our analysis, which included population density, this association with the highest quartile of exposure was still evident (adjusted odds ratio [AOR], 3.48 [95% CI, 1.81-6.83]), and living in an urban area, compared with living in a rural area, was not associated with autism (AOR, 0.86 [95% CI, 0.56-1.31]). When we examined traffic-related air pollutant exposures during pregnancy, the highest quartile was also associated with autism risk (AOR, 1.98 [95% CI, 1.20-3.31]) compared with the lowest quartile. We further divided the pregnancy into 3 trimesters and modeled traffic-related air pollution based on these intervals. During all 3 trimesters of pregnancy, we found associations with the highest quartile of exposure (≥31.8 ppb), compared with the lowest quartile (≤9.7 ppb), and autism (Table 2). Inclusion of demographic and socioeconomic variables in the models did not greatly alter these associations (Table 2).

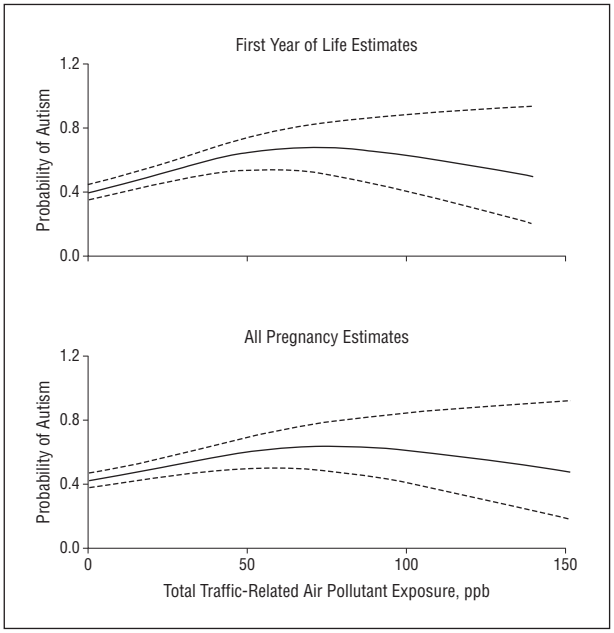

Figure. Probability of autism by increasing level of children's exposure to traffic-related air pollution during the first year of life and during gestation. The dashed lines indicate the 95% CI.

Because our quartile-based categories indicated that there is a threshold upon which traffic-related air pollutant exposure is detrimental, we also examined the relationship between traffic-related air pollutant exposure and autism using smoothed models for the first year of life and all of pregnancy. An increasing probability of autism was seen with increasing traffic-related air pollutant estimates, with the odds reaching a plateau when these estimates were above 25 to 30 ppb (**Figure**).

REGIONAL AIR POLLUTANT EXPOSURE

The higher levels of exposure to $PM_{2.5}$, PM_{10}, and nitrogen dioxide based on the Environmental Protection Agency's regional air quality monitoring program were associated with an increased risk of autism (**Table 3**). Specifically, for an 8.7-unit increase (micrograms per cubic meter) in $PM_{2.5}$ (corresponding to twice the standard deviation of the $PM_{2.5}$ distribution) exposure during the first year of life, children were 2.12 times more likely to have autism. Increases were also present for pregnancy and trimester-specific estimates of $PM_{2.5}$, with the smallest effects present in the first trimester. For PM_{10}, a 14.6-unit increase (micrograms per cubic meter) during the first year was associated with twice the risk of autism (Table 3). Associations were present for pregnancy and for each trimester, with the first trimester having the smallest magnitude. We did not find associations between levels of regional ozone and autism. Regional nitrogen dioxide exposure during the first year was associated with a 2-fold risk of autism. Similar effects were identified for nitrogen dioxide exposure during pregnancy. Although exposure during each of the 3 trimesters was associated with autism, the effects of the first trimester were the smallest. For all regional pollutant measures, adjustment for demographic and socioeconomic

Adjusted[b]	1.48 (1.40-1.57)	1.83 (1.35-2.47)	1.04 (0.84-1.29)	1.61 (1.15-2.25)
Third trimester				
Crude	1.39 (1.11-1.75)	1.61 (1.21-2.13)	1.03 (0.84-1.27)	1.65 (1.19-2.27)
Adjusted[b]	1.40 (1.11-1.77)	1.61 (1.20-2.14)	1.03 (0.83-1.26)	1.64 (1.18-2.29)

Abbreviations: $PM_{2.5}$, particulate matter less than 2.5 μm in aerodynamic diameter; PM_{10}, particulate matter less than 10 μm in aerodynamic diameter.

[a] Regional pollution effects reflect risk of autism based on 2 SDs from the mean value, specifically per increase of 8.7 $\mu g/m^3$ of $PM_{2.5}$, 14.6 $\mu g/m^3$ of PM_{10}, 14.1 ppb of nitrogen dioxide, and 16.1 ppb of ozone.

[b] Models adjusted for male sex of child, child's ethnicity (Hispanic vs white; black/Asian/other vs white), maximum education of parents (parent with highest of 4 levels: college degree or higher vs some high school, high school degree, or some college education), maternal age (>35 years vs ≤35 years), and prenatal smoking (self-report of ever vs never smoked while pregnant).

variables did not alter the associations. As with traffic-related air pollution, when we included population density in the models that included exposure during the first year of life, the associations with $PM_{2.5}$, PM_{10}, and nitrogen dioxide did not change, nor did they change when living in an urban area vs a rural area was included (data not shown).

TRAFFIC-RELATED AIR POLLUTION, $PM_{2.5}$, AND PM_{10}

Because pairwise correlations between traffic-related air pollution and $PM_{2.5}$ and between traffic-related air pollution and PM_{10} were moderate, we included both in models to examine whether local pollution estimates (traffic-related air pollution) and regional pollution measures ($PM_{2.5}$ and PM_{10}) were independently associated with autism. In these analyses, we included the same set of covariates already described in the single pollutant analysis. When examined in the same model, the top quartile of traffic-related air pollutant exposure (AOR, 2.37 [95% CI, 1.28-4.45]) and the exposure to $PM_{2.5}$ (AOR, 1.58 [95% CI, 1.03-2.42]) during the first year of life remained associated with autism. Examining both traffic-related air pollution and PM_{10}, we found that the top quartile of traffic-related air pollutant exposure (AOR, 2.36 [95% CI, 1.28-4.43]) and the exposure to PM_{10} (AOR, 1.61 [95% CI, 1.06-2.47]) remained associated with autism. For the all pregnancy time interval, we found that the top quartile of traffic-related air pollutant exposure (AOR, 2.42 [95% CI, 1.32-4.50]) and the exposure to $PM_{2.5}$ (AOR, 1.60 [95% CI, 1.07-2.40]) were associated with autism when examined in the same model. Similarly, both the top quartile of traffic-related air pollutant exposure (AOR, 2.33 [95% CI, 1.27-4.36]) and the exposure to PM_{10} (AOR, 1.68 [95% CI, 1.11-2.53]) remained associated with autism when examined jointly.

COMMENT

Our study found that local estimates of traffic-related air pollution and regional measures of $PM_{2.5}$, PM_{10}, and nitrogen dioxide at residences were higher in children with autism. The magnitude of these associations appear to be most pronounced during late gestation and early life, although it was not possible to adequately distinguish a period critical to exposure. Children with autism were 3 times as likely to have been exposed during the first year of life to higher modeled traffic-related air pollution compared with control children with typical development. Similarly, exposure to traffic-related air pollution during pregnancy was also associated with autism. Examination of traffic-related air pollution using an additive logistic model demonstrated a potential threshold near 25 to 30 ppb beyond which the probability of autism did not increase. Exposure to high levels of regional $PM_{2.5}$, PM_{10}, and nitrogen dioxide were also associated with autism. When we examined $PM_{2.5}$ or PM_{10} exposure jointly with traffic-related air pollutant exposure, both regional and local pollutants remained associated with autism, although the magnitude of the effects decreased.

We previously reported an association between living near a freeway (based on the location of the birth and third trimester address) and autism.[7] That result relied on simple distance metrics as a proxy for exposure to traffic-related air pollution. The present study builds on that result, demonstrating associations with both regional particulate and nitrogen dioxide exposure and to dispersion-modeled exposure to the near-roadway traffic mixture accounting for traffic volume, fleet emission factors, and wind speed and direction, in addition to traffic proximity. The results provide more convincing evidence that exposure to local air pollution from traffic may increase

the risk of autism. Demographic or socioeconomic factors did not explain these associations.

Toxicological and genetic research suggests possible biologically plausible pathways to explain these results. Concentrations of many air pollutants, including diesel exhaust particles and other PM constituents, are increased near freeways and other major roads, and diesel exhaust particles and polycyclic aromatic hydrocarbons (commonly present in diesel exhaust particles) have been shown to affect brain function and activity in toxicological studies.[19-23] Polycyclic aromatic hydrocarbons have been shown to reduce expression of the *MET* receptor tyrosine kinase gene, which is important in early life neurodevelopment and is markedly reduced in autistic brains.[24,25] Other research indicates that traffic-related air pollution induces inflammation and oxidative stress after both short- and long-term exposure, processes that mediate the effects of air pollution on respiratory and cardiovascular disease and other neurological outcomes.[26-29] Data examining biomarkers suggest that oxidative stress and inflammation may also be involved in the pathogenesis of autism.[30-33]

Emerging evidence suggests that systemic inflammation may also result in damage to endothelial cells in the brain and may compromise the blood-brain barrier.[29] Systemic inflammatory mediators may cross the blood-brain barrier, activating brain microglia, and peripheral monocytes may migrate into the pool of microglia.[34-36] In addition, ultrafine particles ($PM_{0.1}$) may penetrate cellular membranes.[37,38] These particles translocate indirectly through the lungs and from the systemic circulation or directly via the nasal mucosa and the olfactory bulb into the brain.[39,40] Toxicity may be mediated by the physical properties of PM or by the diverse mixture of organic compounds, including polycyclic aromatic hydrocarbons, and oxidant metals adsorbed to the surface.[29] Neurodevelopmental effects of polycyclic aromatic hydrocarbons may be mediated by aryl hydrocarbon hydroxylase induction in the placenta, decreased exchange of oxygen secondary to disruption of placental growth factor receptors, endocrine disruption, activation of apoptotic pathways, inhibition of the brain antioxidant-scavenging system resulting in oxidative stress, or epigenetic effects.[21]

Our study draws on a rich record of residential locations of children with typical development and children with autism across California, allowing us to assign modeled pollutant exposures for developmentally relevant time points. However, our results could also be affected by unmeasured confounding factors associated with both autism and exposure to traffic-related air pollution. Although we did not find that including demographic or socioeconomic variables altered our estimates of effect, confounding by other factors could still occur. These might include lifestyle, nutritional, or other residential exposures, if they were associated with traffic-related air pollution or PM. We have also not explored indoor sources of pollution, such as indoor nitrogen oxide or secondhand tobacco smoke, although prenatal smoking was examined and did not influence the associations of ambient pollution with autism. In addition, confounding could have occurred if proximity to diagnosing physicians or treatment centers was also associated with exposure. We included population density as an adjustment in an analysis using estimates from the first year of life to examine the sensitivity of our results to urban or rural locations, for which population density is a surrogate. We did not find that living in a more densely populated area altered the association between risk of autism and exposure to traffic-related air pollution or regional pollutants. Despite our attempts to use residential history to examine specific time windows of vulnerability, to incorporate meteorology into our traffic-related air pollutant models, and to include pollutants with seasonal variation, we are currently unable to disentangle the trimester-specific effects during the first year of life because of the high level of correlation across these time periods.

Exposures to traffic-related air pollution, PM, and nitrogen dioxide were associated with an increased risk of autism. These effects were observed using measures of air pollution with variation on both local and regional levels, suggesting the need for further study to understand both individual pollutant contributions and the effects of pollutant mixtures on disease. Research on the effects of exposure to pollutants and their interaction with susceptibility factors may lead to the identification of the biologic pathways that are activated in autism and to improved prevention and therapeutic strategies. Although additional research to replicate these findings is needed, the public health implications of these findings are large because air pollution exposure is common and may have lasting neurological effects.

Childhood Incident Asthma and Traffic-Related Air Pollution at Home and School

Rob McConnell,[1] Talat Islam,[1] Ketan Shankardass,[2] Michael Jerrett,[3] Fred Lurmann,[4] Frank Gilliland,[1] Jim Gauderman,[1] Ed Avol,[1] Nino Künzli,[5] Ling Yao,[6] John Peters,[1] and Kiros Berhane[1]

[1]University of Southern California, Los Angeles, California, USA; [2]St. Michael's Hospital, Toronto, Ontario, Canada; [3]University of California, Berkeley, California, USA; [4]Sonoma Technology, Inc, Petaluma, California, USA; [5]Swiss Tropical and Public Health Institute, Basel and University of Basel, Switzerland; [6]United Health Group, City of Hope Hospital Medical Center, Los Angeles, California, USA

Background: Traffic-related air pollution has been associated with adverse cardiorespiratory effects, including increased asthma prevalence. However, there has been little study of effects of traffic exposure at school on new-onset asthma.

Objectives: We evaluated the relationship of new-onset asthma with traffic-related pollution near homes and schools.

Methods: Parent-reported physician diagnosis of new-onset asthma (n = 120) was identified during 3 years of follow-up of a cohort of 2,497 kindergarten and first-grade children who were asthma- and wheezing-free at study entry into the Southern California Children's Health Study. We assessed traffic-related pollution exposure based on a line source dispersion model of traffic volume, distance from home and school, and local meteorology. Regional ambient ozone, nitrogen dioxide (NO_2), and particulate matter were measured continuously at one central site monitor in each of 13 study communities. Hazard ratios (HRs) for new-onset asthma were scaled to the range of ambient central site pollutants and to the residential interquartile range for each traffic exposure metric.

Results: Asthma risk increased with modeled traffic-related pollution exposure from roadways near homes [HR 1.51; 95% confidence interval (CI), 1.25–1.82] and near schools (HR 1.45; 95% CI, 1.06–1.98). Ambient NO_2 measured at a central site in each community was also associated with increased risk (HR 2.18; 95% CI, 1.18–4.01). In models with both NO_2 and modeled traffic exposures, there were independent associations of asthma with traffic-related pollution at school and home, whereas the estimate for NO_2 was attenuated (HR 1.37; 95% CI, 0.69–2.71).

Conclusions: Traffic-related pollution exposure at school and homes may both contribute to the development of asthma.

Key words: air pollution, asthma, child, epidemiology, vehicular traffic. *Environ Health Perspect* 118:1021–1026 (2010). doi:10.1289/ehp.0901232 [Online 6 April 2010]

The role of air pollution in the development of new-onset asthma remains controversial, and the contribution of this environmental risk factor to the pandemic remains unclear (Eder et al. 2006; Sarnat and Holguin 2007). Although increasing evidence indicates that living near heavy traffic is associated with increased rates of asthma, some well-designed studies have found only weak or no associations (Heinrich and Wichmann 2004; Oftedal et al. 2009).

These inconsistencies may reflect incomplete assessment of exposures to traffic in the microenvironments in which children spend most of their time. Exposure at locations other than home, especially at school where children spend a large proportion of waking hours and may engage in physical activity that would increase the ventilation rate and dose of inhaled pollutants, may have strong influences on occurrence of asthma. However, few studies have examined the effect of traffic-related pollution at schools on asthma rates among children. Two cross-sectional Dutch studies that examined this question reported higher rates of respiratory symptoms among children in schools near roadways with heavy traffic, especially truck traffic (Janssen et al. 2003; van Vliet et al. 1997). A northern California study found that schools downwind from busy freeways had higher concentrations of oxides of nitrogen (NO_x) and higher asthma prevalence rates (Kim et al. 2004). However, in a subsequent analysis of these same data, the effect of school exposure was attenuated and no longer significant after adjusting for modeled residential traffic-related exposure (Kim et al. 2008).

Nitrogen dioxide (NO_2) is routinely measured at regulatory monitoring stations. However, these measurements reflect both background regional concentrations and local sources near the stations. Some studies have assessed local exposure to traffic-related pollution using measured NO_2 (or NO_x) as surrogate for the complex mixture of traffic-related pollutants that occurs in close proximity to roadways (Brauer et al. 2007; Gauderman et al. 2005; Jerrett et al. 2008; Kim et al. 2004; Kramer et al. 2000; Nordling et al. 2008). NO_2 can feasibly be measured at a large number of locations, and it has been widely used as a proxy for the mixture of traffic-related pollutants that vary markedly depending on distance from roadways, season, wind speed, and wind direction. However, the mixture of pollutants in close proximity to roadways includes transition metals and organic aerosols, which are more plausible causes of asthma than NO_2 (Li et al. 2003).

The Southern California Children's Health Study (CHS) was designed to investigate the chronic effects of air pollution on respiratory health. Previous analyses have found associations of asthma with residential distance to major roads and modeled and measured pollutant markers for intracommunity variation in exposure to traffic (Gauderman et al. 2005; Jerrett et al. 2008; McConnell et al. 2006; Salam et al. 2007b) and with regional pollutants in susceptible children (Islam et al. 2008; McConnell et al. 2002). In the current analysis, a prospective, longitudinal evaluation of new cases of asthma has allowed assessment of exposure before the development of asthma in an ongoing cohort of school children recruited in kindergarten and first grade, an age at which physician-diagnosed asthma becomes reliable and valid (Martinez et al. 1995). Exposure to traffic-related pollutants has been estimated at participating schools and at residences. In addition, NO_2, ozone (O_3), and particulate matter < 10 μm (PM_{10}) and < 2.5 μm in aerodynamic diameter ($PM_{2.5}$) have been measured continuously during the lifetime of most study participants at a location in each community representative of exposure in the neighborhoods where children live (Kunzli et al. 2003; McConnell et al. 2006). This design allowed examination of the joint effects of traffic-related pollution exposure at school and home and of regional measured pollution at community

monitors. We hypothesized that exposure at school and home both contribute to the risk of new-onset asthma.

Methods

Study population. Characteristics of this cohort have been described previously (McConnell et al. 2006). Briefly, 5,349 children attending kindergarten and first grade were enrolled into a new CHS cohort during the 2002–2003 school year from 45 schools in 13 communities. Communities were selected to represent the range and mixture of regional particulate pollutants, NO_2, and O_3 in southern California.

[a]Numbers may not add up to 2,497 in some subgroups because of missing data. [b]Crude incidence (IR) rate per 1,000 person-years. [c]Occurred in 2003 during first year of follow-up.

Parents provided informed consent and completed a baseline and yearly questionnaire with information about demographic characteristics, respiratory illness, and risk factors for asthma at study entry. Children with a history of physician-diagnosed asthma at study entry (n = 715, 13.4%) were excluded from this follow-up, because the focus was on risks for incident asthma. To ensure that the study population was free of any previously undiagnosed asthma, we then also excluded children with a history of wheeze (n = 868, 16.2%) and additional children with missing information about wheeze, or missing or a "don't know" answer about asthma (n = 394, 7.4%). These exclusions resulted in a total of 3,372 children classified as disease free at baseline. We excluded another 340 children with no residential traffic information because home address could not be geocoded [disproportionately from a single community, as described in the Supplemental Material (doi:10.1289/ehp.0901232)] and another 535 children who did not participate in any of the annual follow-up questionnaires. The final sample included 2,497 children.

New-onset asthma and covariates. Children with physician-diagnosed asthma reported on a yearly questionnaire during 3 years of follow-up were defined to have new-onset asthma. Children missing questionnaires in any year continued to contribute person-time to the models until they answered yes (at which time they were censored) or were lost to follow-up. The date of new onset of asthma could not be precisely defined. Therefore, the date of onset was assigned to the midpoint of the interval between the date of the questionnaire when asthma diagnosis was first reported and the date of the previous questionnaire reporting asthma status, and this date was used for estimating follow-up time in all statistical analyses. Sociodemographic characteristics, exposure to cigarette and wildfire smoke, health insurance, housing characteristics, history of allergy, and parental asthma were assessed by questionnaire [see Supplemental Material (doi:10.1289/ehp.0901232) for details].

Community ambient air pollution measurements. Ambient levels of O_3, NO_2, PM_{10}, and $PM_{2.5}$ were measured continuously during follow-up at a central site monitor in each community, as described in the Supplemental Material (doi:10.1289/ehp.0901232) and in previous reports (Peters et al. 1999). Because there is marked diurnal variation in O_3 and exposure occurs largely between 1000 and 1800 hours, this average was used in all analyses. Average temperature and relative humidity were also obtained during follow-up from measurements at the monitoring stations.

Local traffic-related pollutant exposure. Exposure to traffic-related pollution was estimated using methods described previously (McConnell et al. 2006), and several metrics

of local traffic related exposure were compiled. Participant residence and school addresses were geocoded, and we estimated distances to the nearest freeway or other highways or arterial roads and traffic density within 150 m of each child's residence and school. Concentrations of pollutants from local vehicle emissions at homes and schools were estimated separately from freeway and nonfreeway sources, using a line source dispersion model of the incremental contribution by these nearby sources to oxides of nitrogen above the regional background levels (Benson 1989). The modeled annual concentration estimates (parts per billion) were based on distance to roadways, vehicle counts, vehicle NO_x emission rates, wind speed and direction, and height of the mixing layer in each community. However, these modeled exposures reflect the mixture of multiple pollutants from nearby traffic, and the high correlation of pollutants in the mixture precludes identifying the effect of any specific pollutant in the mixture, as described in the Supplemental Material (doi:10.1289/ehp.0901232). For brevity, these modeled exposures will be referred to as traffic-related pollutants (TRP). An estimate of combined school and home exposure to traffic was made by weighting the estimates by approximate time at school (35 hr weekly, or 21%) and assigning the remaining 79% of time to the home. Health effect estimates based on models in which the contribution of school to the combined exposure was reduced to 16% to account for a lack of school exposure during summer recess were very similar (data not shown).

Statistical methods. We fitted a multilevel Cox proportional hazards model that allows for assessment of residual variation in time to asthma onset and also for clustering of children around schools and communities (Ma et al. 2003). Letting u_i and u_{ij} denote community- and school (within community)-level random effects, with u_{ij} assumed to be positive and independent conditional on u_i, we fit the following model:

$$h_{ijl}(t) = h_{0s}(t)\, u_{ij}\, exp(\beta X_{ijl} + \delta^T Z_{ijl}), \quad [1]$$

where, for the lth subject in the ith community, and jth school, $h_{ijl}(t)$ is the hazard function at age t; $h_{0s}(t)$ is the baseline hazard function in stratum s (defined by age at study entry and sex), X_{ijl} is a traffic pollution exposure metric, and Z_{ijl} are other individual covariates, such as secondhand smoke exposure, pets in the home, and other possible confounders. All models included race/ethnicity.

The model allowed for joint evaluation of the effects of exposure to traffic-related pollutants at homes and at schools and to ambient pollutants measured at community central sites, with effects scaled to the interquartile range (IQR) for each metric of residential exposure (e.g., for TRP from the line source dispersion model) and to the total range across the 13 communities, respectively. Traffic exposure at homes and school were correlated. Therefore, in models including both exposures, home traffic estimates were deviated from the corresponding school metric to minimize the chance of collinearity and allow for valid independent effect estimates (for example, r-square for school with deviated home TRP were < 0.38 for freeway, nonfreeway, and total TRP). Although the school-specific estimates of exposure were of primary interest, models including the average residential exposure corresponding to each school (and residential exposures deviated from this average) were also fitted [see Supplemental Material (doi:10.1289/ehp.0901232) for details]. Potential confounders were evaluated one at a time, based on whether the estimates for the pollutant associations changed by > 10%. We assessed heterogeneity of traffic pollution effects by level of community central site regional pollutant measurements by comparing nested models using a partial likelihood ratio test with and without interaction terms. We examined any potential nonlinearity in the exposure–response relationship using cubic spline terms, piecewise polynomials joined smoothly at a number of break points (Hastie and Tibshirani 1990), for the exposure terms and comparing the nested models using a partial likelihood ratio test. All analyses were conducted using software designed to run within R software (R Development Core Team, Vienna, Austria) for implementing random effects Cox proportional hazards models (Krewski et al. 2009; Ma et al. 2003). All hypotheses were tested assuming a 0.05 significance level and a two-sided alternative hypothesis.

Results

Most of the 2,497 disease-free children included in this analysis were ≤ 6 years of age (range, 4.8–9.0 years) at study entry (Table 1). There were 120 new cases of asthma, resulting in an incidence rate of approximately 18.7 cases per 1,000 person-years (based on 6,434 person-years of follow-up). Rates did not differ by age at study entry or sex. About half the children were Hispanic whites, and they had the lowest rates of asthma (16.8/1,000 person years), whereas African Americans had the highest rate (33.9/1,000 person-years), but this was based on only six cases. Substantially higher rates were also observed for children with history of allergy, parental history of asthma, and maternal smoking during pregnancy.

Both residential and school TRP metrics had a wide range with skewed distributions (Table 2). For example, the mean and median for nonfreeway residential TRP were 7.3 and 6.1 ppb, respectively, and the IQR was 8.0 ppb, with a total range from 0.08 to a maximum of 55.1 ppb. A few homes and schools had very low freeway TRP (largely in a single community that has no freeways). There was ≥ 3-fold variation in the multiyear average NO_2, PM_{10}, and $PM_{2.5}$ from the lowest to highest pollution community for measurements at the central site monitors. O_3 levels varied by 2-fold.

The associations of new-onset asthma were strongest with nonfreeway TRP. The hazard ratio (HR) at homes was 1.51; 95% confidence interval (CI), 1.25–1.81; $p < 0.001$

Table 2. Distribution of annual average residential traffic-modeled pollution and of community central site measurements.

	Mean	Median	IQR	Minimum	Maximum	Range
Residential traffic (ppb)						
Nonfreeway TRP	7.3	6.1	8	0.08	55.1	55
Freeway TRP	11.1	7.3	13	< 0.0001	134.5	134.5
Total TRP	18.4	14.6	20.9	0.23	144.1	143.9
School traffic (ppb)						
Nonfreeway TRP	6.1	5.9	5.9	0.3	19.7	19.4
Freeway TRP	10.9	8.2	15.2	< 0.0001	39.9	39.9
Total TRP	17	11.9	18.5	0.7	51.4	50.7
Central-site measurements						
NO_2 (ppb)	20.4	21.8	12.8	8.7	32.3	23.6
PM_{10} (μg/m^3)	35.5	34	11.7	17.6	61.5	43.9
$PM_{2.5}$ (μg/m^3)	13.9	15.1	9.7	6.3	23.7	17.4
1000–1800 hours O_3 (ppb)	44.6	43.6	11.1	29.5	59.8	30.3

Table 3. Association between new-onset asthma and modeled exposure at home and school.

Traffic-related exposure[a]	Home HR[b] (95% CI)	School HR[b] (95% CI)	Combined[c] HR[b] (95% CI)
Nonfreeway TRP	1.51 (1.25–1.81)*	1.45 (1.06–1.98)	1.61 (1.29–2.00)*
Freeway TRP	1.12 (0.95–1.31)	1.08 (0.86–1.34)	1.12 (0.94–1.35)
Total TRP	1.32 (1.08–1.61)**	1.20 (0.91–1.58)	1.34 (1.07–1.68)

[a]Scaled to the IQR at homes for each metric (from Table 2). [b]HR (95% CI, adjusted for race/ethnicity and for baseline hazards strata of age at study entry and sex) with random effects for community and school. [c]Combined weighted for time at home and school. *$p < 0.001$. **$p < 0.01$.

(Table 3). The HR for exposure at schools was almost as large as for residential exposure (HR = 1.45; 95% CI, 1.06–1.98), and the combined average exposure weighted for time at school and home had a slightly stronger association (HR = 1.61; 95% CI, 1.29–2.00). These associations were not confounded by any of the covariates in Table 1 or by community relative humidity, which we have previously found to confound TRP exposure (Jerrett et al. 2008). There also were no significant interactions of either residential or school nonfreeway TRP with sex, allergy, or parental history of asthma, which we have previously shown modified effects of traffic exposure (McConnell et al. 2006). Similar effect sizes were observed in sensitivity analyses restricted to lifetime residents at the same address, analyses excluding children diagnosed in the first year of follow-up and excluding children who changed schools during the follow-up period. There was little evidence of nonlinearity in the exposure–response relationship based on sensitivity analyses comparing the fit of a smoothed cubic spline model of asthma with a linear model (p-value > 0.80) for the partial likelihood ratio test for models with 3 and 5 knots compared with the linear model. Weaker associations were observed with total TRP at homes (HR = 1.32; 95% CI, 1.08–1.61) and school (HR = 1.20; 95% CI, 0.91–1.58). There were weaker and nonsignificant associations with TRP modeled from freeways. Nonfreeway TRP was moderately to strongly correlated with freeway TRP at homes (R = 0.64) and at schools [R = 0.70; Supplemental Material, Table E-1, (doi:10.1289/ehp.0901232)]. However, in models co-adjusted for freeway and nonfreeway TRP, the nonfreeway effect estimates for school and home were similar to the unadjusted estimates.

Of the regional community central-site pollutants, NO_2 was associated with more than double the risk of new-onset asthma (HR = 2.17; 95% CI, 1.18–4.00; p = 0.01) over the range of exposure (23.6 ppb) across the 13 study communities (Table 4). In a model with NO_2, school and residential nonfreeway TRP exposure, the estimate for NO_2 was attenuated (HR = 1.37; 95% CI, 0.69–2.71; Table 5). However, the adjusted associations of asthma with nonfreeway TRP at homes (HR = 1.46) and schools (HR = 1.45) in Table 5 were very similar to the unadjusted effect estimates (HR = 1.51 and 1.45, respectively, shown in Table 3). In sensitivity analyses, a similar pattern of attenuation of regional NO_2 effect estimates was observed in models weighted for time at school and home (results not shown), and in models adjusted for total (freeway plus nonfreeway) TRP exposure at school and home [Supplemental Material, Table E-2 (doi:10.1289/ehp.0901232)]. There were neither statistically significant interactions of central site pollutants with residential TRP nor any consistent patterns suggestive of different effects in high and low regional pollutant communities (results not shown). We have previously shown that O_3 modified the association of team sports participation with new-onset asthma in an older cohort (McConnell et al. 2002), but there was neither a main effect of sports nor confounding or effect modification of effects of residential TRP or ambient central monitor pollutant exposure.

Distance to freeways and other major roads and traffic volume on those roads have been used in other studies as independent predictors of traffic exposure, so we examined the distribution [Supplemental Material, Table E-3 (doi:10.1289/ehp.0901232)] and correlations of these metrics (Supplemental Material, Table E-1) and the association at school and home with asthma (Supplemental Material, Tables E-4 and E-5). In general, these exposure metrics were weakly to moderately correlated with the TRP metrics but were not consistently associated with asthma in our data set.

Discussion

The study is unique in its prospective assessment of the relationship of new-onset childhood asthma to community regional air pollution and near-source traffic-related exposure at home and in a large number of schools. The results indicate that associations of asthma with traffic-related pollution from nearby sources at schools were independent of estimated effects of exposures at homes, and these effects were of similar size over a range of exposure common in Southern California. Evidence of a school effect comparable with that associated with the much larger amount of time spent at home could potentially be explained by physical education and other exercise at school that may increase ventilation rate and dose of pollutants to the lungs and thereby increase the risk associated with exposure. Traffic-related pollutant levels may also be considerably higher during the morning hours, when children are arriving at school, especially during temperature inversions that occur largely in the winter months when children are attending school (Kim et al. 2002; Ning et al. 2007). It is possible that school exposure may have reflected time spent in other locations in the child's neighborhood rather than school-specific exposure, and this possibility merits further investigation. However, time at school during the school year accounts for more than one-third of all waking hours, and in this age group it is likely that most of the child's remaining nonschool time was spent at home (Xue et al. 2004). The increased risk associated with TRP could not be explained by confounders commonly associated with asthma or by ambient NO_2 or other currently regulated regional pollutants measured at the central-site monitoring stations. These results strengthen an emerging body of evidence from both toxicologic and epidemiologic studies that air pollutants from nearby traffic contribute to the development of asthma (Salam et al. 2008).

NO_2 measured at community monitoring stations has been associated with wheeze prevalence in an older CHS cohort (Peters et al. 1999) and with increased risk of asthma incidence in a Japanese cohort (Shima et al. 2002). We have recently reported associations of both incident and prevalent asthma with ambient residential NO_2 measured outside homes of a relatively small sample of children from another CHS cohort in many of the same communities, but NO_2 in that study was a marker for intracommunity variation in the mixture of TRPs (Gauderman et al. 2005; Jerrett et al. 2008). Other studies also indicate that associations of respiratory disease with intracommunity variation in NO_2 reflect the effects of other TRP rather than NO_2 (Kramer et al. 2000). A study that measured NO_2 and NO_x in central neighborhood

Table 4. Association of new-onset asthma with community central site pollutant measurements.

Pollutant	HR[a] (95% CI)
NO_2	2.17 (1.18–4.00)
PM_{10}	1.35 (0.64–2.85)

Central site pollutant	HR[b] (95% CI) for ambient pollutant, adjusted for TRP at home and school	HR[b] (95% CI) for home TRP, adjusted for school TRP and ambient pollutant	HR[b] (95% CI) for school TRP, adjusted for home TRP and ambient pollutant
NO_2	1.37 (0.69–2.71)	1.46 (1.16–1.84)*	1.45 (1.03–2.06)
PM_{10}	1.40 (0.62–3.17)	1.46 (1.16–1.85)*	1.53 (1.10–2.12)*
$PM_{2.5}$	1.30 (0.66–2.56)	1.48 (1.19–1.85)*	1.49 (1.07–2.08)
O_3	1.01 (0.49–2.11)	1.50 (1.20–1.86)*	1.54 (1.10–2.14)*

[a]Mutually adjusted across each row (i.e., effect of each community pollutant was examined separately in a model including both home and school TRP). [b]HR (95% CI) for central-site pollutants scaled across the range of exposure in the 13 communities (23.6 ppb for NO_2, 43.9 μg/m^3 PM_{10}, 17.4 μg/m^3 $PM_{2.5}$, and 30.3 ppb for 1000–1800 hours O_3); household nonfreeway TRP was deviated from school, scaled to the IQR for home exposure (8 ppb from Table 2). *p < 0.01.

locations found that associations with asthma were attenuated by adjustment for modeled residential traffic exposure (Kim et al. 2004, 2008). In the current study, the attenuated association between asthma and NO_2 continuously measured at the community monitor in models with adjustment for TRP also suggests that NO_2 was not causally related to asthma. However, interpretation of this result is not clear because exposure measured at the community monitor may have misclassified exposures of children in parts of the community with significant local sources of NO_2. We did not find evidence for main effects of regional O_3 and PM with asthma, consistent with results from previous analyses in older CHS cohorts, although we have previously shown that O_3 modified the effect of outdoor exercise in a genetically susceptible subgroup (Islam et al. 2009; McConnell et al. 2002).

Associations with asthma were significant for TRP exposure estimates modeled from local nonfreeway roadway proximity, traffic volume, and meteorology. There was little evidence for an effect of major roadway proximity alone, for traffic density, or for pollution from freeways. The absence of a freeway TRP effect suggests that causal pollutants may be highly reactive, resulting in steep spatial gradients from freeway sources and little exposure at the longer distances of homes and schools to freeways compared with distance to other major roads [Supplemental Material, Table E-3 (doi:10.1289/ehp.0901232)]. Several previous studies have found that the largest gradients in traffic-related pollutants occur within 150 m from roadways (Gilbert et al. 2003; Zhu et al. 2002), and variability has often been best explained by traffic volume within 300 m (Briggs et al. 2000; Gilbert et al. 2003; Ross et al. 2006). High-volume traffic on secondary roads may also produce pollutants resulting from frequent stops and accelerations, which have been found to be associated with asthma symptoms (Ryan et al. 2005). However, in an older cohort from some of these same communities, we observed associations of freeway-modeled exposures and residential freeway proximity with respiratory outcomes (Gauderman et al. 2005, 2007). Different traffic metric associations with respiratory health may have been due to variation in the distribution of freeway and nonfreeway traffic around homes in the different cohorts and the relatively small number of children living near freeways (< 7% within 150 m in the current cohort). It is also possible that the accuracy of exposure models for the freeway and nonfreeway sources varied in the two cohorts or that the greater mobility of older children resulted in health effects associated with spending time in areas such as parks in close proximity to freeways near homes.

An important distinction between the TRP and simpler traffic metrics is the inclusion of meteorology (average annual wind speed and direction and height of the mixing layer) in addition to proximity and volume. Traffic density alone [Supplemental Material, Table E-4 (doi:10.1289/ehp.0901232)] and proximity to a major roadway (Supplemental Material, Tables E-4 and E-5) had weaker positive associations with incident asthma that were not statistically significant. Therefore, inconsistent findings in some of the (largely cross-sectional) studies that have evaluated associations with asthma (Heinrich and Wichmann 2004) may reflect the failure to account for the impact of meteorology on exposure. We have recently measured NO_x at > 900 locations in these communities. Approximately two thirds of the within-community variability in NO_x was explained by TRP, a substantially higher amount of variation than was explained by any other traffic metric (unpublished data). We have also previously observed that both TRP and residential traffic proximity were associated with increased asthma prevalence in this cohort (McConnell et al. 2006).

The prospective design is a strength of this study. In other prospective studies of birth cohorts in Sweden and the Netherlands, modeled traffic-related pollutants, including NO_x and/or $PM_{2.5}$, were associated with incidence of wheeze and atopy (Nordling et al. 2008) and doctor-diagnosed asthma (Brauer et al. 2007) in children < 5 years of age, when the diagnosis of asthma may be difficult to distinguish from transient wheeze not predictive of asthma. As these cohorts mature, the relationship to asthma is likely to become more clear. For example, associations between $PM_{2.5}$ light absorption, roadway proximity, and asthmatic bronchitis and atopy were found in a study of two German birth cohorts that followed some children to 6 years of age (Morgenstern et al. 2008). Associations with allergic symptoms in these cohorts were less robust at an earlier age (Gehring et al. 2002). Other recent results from prospective studies of birth cohorts (Gehring et al. 2009) and of children (Shima et al. 2002) followed to older ages have generally shown positive associations between markers of residential TRP and asthma, although a recent Norwegian study found no association with modeled exposure at the birth address of a large cohort of children (Oftedal et al. 2009). Genetic studies examining pathways likely to mediate effects of air pollution also strengthen the causal inference that traffic-related pollutants may cause asthma. We have shown elsewhere that the risk of asthma associated with traffic exposure and with traffic-related ambient PM was modified in a predictable way by functional gene variants in pathways associated with asthma, including inflammation and airway remodeling (Salam et al. 2007a) and oxidative stress (Islam et al. 2008; Salam et al. 2007b). In another analysis of the data from this cohort, we have shown that the estimated effect of TRP was modified by socioeconomic status and psychosocial stress (Shankardass et al. 2009).

There are some limitations to these data. Our conservative estimates of TRP for the center of school buildings are likely to underestimate the exposure of students in buildings closer to the roadways, especially during dropoff and pickup of students at the beginning and end of the school day. The impact of this underestimate of exposure on the assessment of health effects is not clear, although in general it might be expected that this exposure misclassification would be nondifferential with respect to asthma and would result in underestimation of the effect of traffic exposure. Other limitations include the relatively short (3-year) period of follow-up and the retrospective questionnaire assessment of early-life risk factors, as this was not a pregnancy cohort. Our cohort excluded children who left the community before school entry and who had asthma or wheeze at study entry. However, our cohort allowed us to examine risk factors in school children, an age during which there has been little study of new-onset asthma.

Asthma is a clinical syndrome with no sensitive and specific diagnostic test available to confirm clinical assessments. Because of the clinical nature of the assessment, the reported physician diagnosis of asthma we used has been recommended and widely used as a method to classify asthma status in epidemiologic studies, although this approach has limitations (Asher et al. 1995; Burr 1992). If misclassification of true asthma based on this approach were random with respect to exposure to air pollution, then the observed associations would be likely to have underestimated the effect of exposure. Bias could explain our results if asthma misclassification were related also to exposure. This could occur if exposure were associated with access to care and differences in practice among physicians that have the potential to influence asthma diagnosis (Samet 1987). However, adjustment for factors that mediate access to care including family income, parental education, and having medical insurance did not alter our results, indicating that confounding due to differential access to care was unlikely to explain these findings. The validity of questionnaire-reported physician diagnosis has also been established in a subset of CHS participants (Salam et al. 2007a). In addition, any child with a history of wheezing at study entry was excluded from the analysis, so it is unlikely that the exacerbation of undiagnosed prevalent asthma by traffic explained these associations. Loss to follow-up could also potentially result in bias because of selection. Sociodemographic characteristics varied between the analysis cohort and children

not contributing to the analysis because of loss to follow-up or missing or poorly matched geocodes for addresses precluding estimation of residential exposure [Supplemental Material, Table E-6 (doi:10.1289/ehp.0901232)]. Hispanic children were less likely than non-Hispanic white children to be included in the follow-up analysis, as were children without insurance and with lower parental education and income. However, adjusting for these factors had little impact on the pattern of observed effects. In addition, there was little difference between exposure to nonfreeway TRP in the study sample (7.3 ppb) and in the group not included because of loss to follow-up (7.6 ppb). Therefore, it is unlikely that selection bias due to loss to follow-up explained our results.

Conclusions

An estimated 6.2 million children have asthma in the United States, making it the most common chronic disease in childhood (Moorman et al. 2007), and rates have increased markedly in developed countries over the past several decades (Braman 2006). Morbidity results in impaired quality of life for the affected child and other family members, in increased use of health services, and in school absences that have large social and economic costs (Wang et al. 2005). Our results indicate that children exposed to higher levels of traffic-related air pollution at school and home are at increased risk of developing asthma. Almost 10% of public schools in California are located within 150 m of roadways with > 25,000 vehicles daily (Green et al. 2004). Students in urban areas in eastern U.S. cities are even more likely than children in Los Angeles to attend schools near major highways (Appatova et al. 2008). Therefore, exposure to TRP is potentially an important public health problem affecting large populations of children. Planning transportation and other urban development to limit population exposure to traffic exhaust, as well as more effective control of vehicular emissions, may result in substantial long-term public health benefits.

Abstract

BACKGROUND—Air-pollution levels have been trending downward progressively over the past several decades in southern California, as a result of the implementation of air quality– control policies. We assessed whether long-term reductions in pollution were associated with improvements in respiratory health among children.

METHODS—As part of the Children's Health Study, we measured lung function annually in 2120 children from three separate cohorts corresponding to three separate calendar periods: 1994–1998, 1997–2001, and 2007–2011. Mean ages of the children within each cohort were 11 years at the beginning of the period and 15 years at the end. Linear-regression models were used to examine the relationship between declining pollution levels over time and lung-function development from 11 to 15 years of age, measured as the increases in forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) during that period (referred to as 4-year growth in FEV_1 and FVC).

RESULTS—Over the 13 years spanned by the three cohorts, improvements in 4-year growth of both FEV_1 and FVC were associated with declining levels of nitrogen dioxide ($P<0.001$ for FEV_1 and FVC) and of particulate matter with an aerodynamic diameter of less than 2.5 μm ($P = 0.008$ for FEV_1 and $P<0.001$ for FVC) and less than 10 μm ($P<0.001$ for FEV_1 and FVC). These associations persisted after adjustment for several potential confounders. Significant improvements in lung-function development were observed in both boys and girls and in children with asthma and children without asthma. The proportions of children with clinically low FEV_1 (defined as <80% of the predicted value) at 15 years of age declined significantly, from 7.9% to 6.3% to 3.6% across the three periods, as the air quality improved ($P = 0.001$).

CONCLUSIONS—We found that long-term improvements in air quality were associated with statistically and clinically significant positive effects on lung-function growth in children. (Funded by the Health Effects Institute and others.)

In previous investigations, we and others have linked exposure to ambient air pollution with lung-function impairment in children. [1–8] Reduced lung function in children has been associated with an increased risk of asthma. [9] In addition, the adverse effects of air pollution on the lungs in childhood can potentially have long-term effects: lung function lower than the predicted value for a healthy adult has been found to be associated with an increased risk of cardiovascular disease and increased mortality rate.[10–12] Although progress has been made throughout the United States to reduce outdoor levels of several air pollutants, it is not known whether these reductions have been associated with improvements in children's respiratory health.

Southern California has historically been plagued by high levels of air pollution owing to the presence of a large motor-vehicle fleet, numerous industries, the largest seaport complex in the United States, and a natural landscape that traps polluted air over the Los Angeles basin. With mounting scientific evidence of the adverse health effects of air pollution, aggressive pollution- reduction policies have been enacted. These have included strategies to control pollution from mobile and stationary sources, as well as fuel and consumer-product reformulations. As a result, air-pollution levels have been trending downward over the past several decades in southern California.

Improvements in air quality over time provide the backdrop for a "natural experiment" to examine the potential beneficial health effects. As part of the 20-year Children's Health Study, three separate cohorts of children have had longitudinal lung-function measurements recorded over the same 4-year age range (11 to 15 years) and in the same five study communities but during different calendar periods. In this study, we examined whether changes that have occurred across these time spans in levels of nitrogen dioxide, ozone, and particulate matter with an aerodynamic diameter of less than 2.5 μm ($PM_{2.5}$), less than 10 μm (PM_{10}), and between 2.5 and 10 μm (coarse particulate matter [PM_{10}–$PM_{2.5}$]) are associated with the development of lung function in children.

METHODS

PARTICIPANTS

The study sample included children recruited from three separate Children's Health Study cohorts (Fig. S1 in the Supplementary Appendix, available with the full text of this article at NEJM. org). The two earlier cohorts (cohorts C and D) enrolled fourth-grade students in 1992–1993 and 1995–1996, respectively, from elementary schools in 12 southern California communities.[13] The third cohort (cohort E) enrolled kindergarten and first-grade students in 2002–2003 from 13 communities, [14] 9 of which overlapped with the 12 cohort C and D communities. Because of budgetary limitations, pulmonary-function testing was conducted in only 5 of the 9 overlapping communities. To facilitate direct comparisons across calendar periods, analyses were restricted to the 5 study communities (Long Beach, Mira Loma, Riverside, San Dimas, and Upland) in which pulmonary-function testing was performed in

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

all three cohorts (Fig. S2 in the Supplementary Appendix). This sample included a total of 2120 children, including 669 in cohort C, 588 in cohort D, and 863 in cohort E.

The study protocol was approved by the institutional review board for human studies at the University of Southern California, and written informed consent was provided by a parent or legal guardian for all study participants.

PULMONARY-FUNCTION TESTING

Trained technicians assisted the students in performing pulmonary-function maneuvers that met the standards of the American Thoracic Society, as described elsewhere.[8] For each child, maximal forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) were measured. For cohorts C and D, pulmonary-function testing was performed annually from 4th through 12th grade (mean ages, 10 to 18 years), with the use of rolling-seal spirometers. In cohort E, pulmonary-function testing was performed every other year, when the children were approximately 11, 13, and 15 years of age, with the use of pressure transducer–based spirometers. Of the 2120 children, 1585 (74.8%) were tested at the beginning (age 11 years) and end (age 15 years) of the follow-up period, whereas the remaining 535 children (25.2%) were tested at 11 but not at 15 years of age.

QUESTIONNAIRES

Written questionnaires regarding each child's general health and personal exposures were completed by the parent or guardian at baseline and by the child participants annually throughout the study thereafter. The questionnaires obtained basic information about the child, including age, sex, self-identified race and ethnic background, insurance coverage, and parental education, as well as the child's health conditions (asthma or acute respiratory illness), tobacco-smoke exposures (personal smoking, secondhand exposure, or in utero exposure), and other exposures.

AIR POLLUTANTS

Outdoor air-pollution monitoring stations in each of the study communities have been continuously measuring regional air pollutants since 1994. Data on hourly or daily concentrations of nitrogen dioxide, $PM_{2.5}$, PM_{10}, and ozone were routinely collected with Federal Reference Method or Federal Equivalent Method instrumentation. A systematic quality-assurance program was in place to review all data. Mean air-pollutant concentrations were calculated for each community over the relevant periods of exposure for each cohort (1994–1997 for cohort C, 1997–2000 for cohort D, and 2007–2010 for cohort E).

STATISTICAL ANALYSIS

The goal of the analyses was to examine the association between long-term improvements in ambient air quality and lung-function development in children from 11 to 15 years of age, measured as the increases in FEV_1 and FVC during that period (hereafter referred to as 4-year growth in FEV_1 and FVC). All available pulmonary-function measurements were used to estimate lung-function growth curves, including measurements at ages ranging from approximately 9 to 19 years in cohorts C and D and 10 to 16 years in cohort E. A previously developed linear-spline model,[5] with knots placed at ages 12, 14, and 16 years, was used to

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

capture the nonlinear pattern of growth during adolescence (see the Supplementary Appendix for details). The model included adjustments for sex, race, Hispanic ethnic background, height, height squared, body-mass index (BMI, the weight in kilograms divided by the square of the height in meters), BMI squared, and presence or absence of respiratory-tract illness on the day of the pulmonary-function test. The model was constructed to yield estimates of the effects of pollutants on 4-year lung-function development (from 11 to 15 years of age) and on mean attained lung function at either 11 or 15 years of age. The range from 11 to 15 years of age was targeted because it covers the overlapping age period of pulmonary-function testing across cohorts. Follow-up over this age range was conducted from 1994 through 1998 in cohort C, from 1997 through 2001 in cohort D, and from 2007 through 2011 in cohort E. The estimated health effect of each pollutant is reported as the expected difference in lung-function growth associated with a difference in exposure equal to the median of the changes in pollution in the five communities over the course of the study period (Table 1).

In addition to examining 4-year growth from 11 to 15 years of age, we analyzed the cross-sectional pulmonary-function measurements obtained for 1585 children at the end of this period (mean age, 15 years) to determine whether changes in air quality over time were associated with clinically important deficits in attained FEV_1 and FVC. Using data from all three cohorts, we developed a linear prediction model for FEV_1 that included adjustments for age, sex, race and ethnic background, height, height squared, BMI, BMI squared, and the presence or absence of respiratory illness. This model explained 61% of the variance in FEV_1 and 69% of the variance in FVC measurements at 15 years of age (i.e., $R^2 = 0.61$ and 0.69, respectively). For each child, we determined whether the ratio of observed to predicted FEV_1 and FVC fell below each of three cutoffs for defining low lung function: 90%, 85%, and 80%. Logistic regression was used to test for temporal trends in the proportion of children with low lung function across cohorts after adjustment for community. A P value of less than 0.05 was considered to indicate statistical significance, under the assumption of a two-sided alternative hypothesis.

RESULTS

CHARACTERISTICS OF THE STUDY PARTICIPANTS

There were slightly more girls than boys (52% vs. 48%) in each of the three cohorts (Table S1 in the Supplementary Appendix). The mean age at the baseline pulmonary-function test was higher in cohort E (11.3 years) than in cohort C (10.9 years) and cohort D (10.9 years). The age-specific mean height did not differ significantly across cohorts at 11, 13, or 15 years of age. There was a significantly higher proportion of Hispanic children in cohort E than in cohorts C and D (58% vs. 31% and 33%, respectively). Cohort E also differed significantly from cohorts C and D with regard to several other factors, including exposure to passive smoke and pets (lower in cohort E) and the proportion of parents with health insurance (higher in cohort E) (Table S1 in the Supplementary Appendix).

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

CHANGES IN AIR QUALITY

Regional air quality has improved dramatically over the course of the Children's Health Study with respect to some pollutants (Fig. 1). The colored bands in Figure 1 represent the 4-year exposure periods for cohorts C (1994–1997), D (1997–2000), and E (2007–2010). For example, the 4-year mean $PM_{2.5}$ level in the community with the highest levels of particulate matter (Mira Loma) declined from 31.5 μg per cubic meter in cohort C to 17.8 μg per cubic meter in cohort E, a 43% reduction (Table S2 in the Supplementary Appendix). All five communities had large declines in levels of $PM_{2.5}$ and nitrogen dioxide. Changes in levels of PM_{10} and ozone over time were more modest (Fig. 1), as were changes in levels of PM_{10}–$PM_{2.5}$ (Fig. S3 in the Supplementary Appendix).

CHANGES IN LUNG-FUNCTION GROWTH

Across all three study cohorts, the mean FEV_1 among girls increased from 2274 ml at 11 years of age to 3150 ml at 15 years of age, for a mean 4-year increase of 876 ml (Table S3 in the Supplementary Appendix). Among boys, the mean FEV_1 was 2311 ml at 11 years of age and 3831 ml at 15 years of age, for a mean 4-year growth of 1520 ml. Similar magnitudes of growth were observed for FVC.

Increases in 4-year growth in both FEV_1 and FVC were associated with reduced levels of nitrogen dioxide, PM_{10}, and $PM_{2.5}$ within all five study communities (Fig. 2). When the effects were averaged across communities, we found that the mean 4-year growth in FEV_1 increased by 91.4 ml per decrease of 14.1 ppb in nitrogen dioxide level ($P<0.001$), by 65.5 ml per decrease of 8.7 μg per cubic meter in PM_{10} level ($P<0.001$), and by 65.5 ml per decrease of 12.6 μg per cubic meter in $PM_{2.5}$ level ($P = 0.008$) (Table 1). At the beginning of follow-up (when participants were 11 years of age), significant increases in mean FEV_1 values were associated with decreases in levels of nitrogen dioxide, PM_{10}, and $PM_{2.5}$ (Table 1). However, the increases in mean FEV_1 at 15 years of age, after 4 years of pollution-affected growth, were even more pronounced. Analogous effects were observed for FVC. Changes in ozone (Fig. 2) and PM_{10}–$PM_{2.5}$ (Fig. S4 in the Supplementary Appendix) were not associated with differences in mean FEV_1 or FVC values at 11 or 15 years of age or with 4-year growth in these values.

The estimated pollution-related effects on 4-year FEV_1 and FVC growth remained significant in sensitivity analyses (Table S4 in the Supplementary Appendix). For example, the associations between improved lung-function development and reduced nitrogen dioxide levels in Table 1 (shown as "base model" in Table S4 in the Supplementary Appendix) remained significant and of similar magnitude when additional adjustment was made for in utero or passive tobacco-smoke exposure, personal smoking, health insurance, parental education, asthma at baseline, or several indoor exposures, including cats, dogs, and mold or mildew. There were significant effects on lung-function growth in both boys and girls, although the magnitude of the air-pollution effect was significantly larger in boys than in girls with respect to both FEV_1 ($P = 0.04$) and FVC ($P = 0.001$). There were also significant pollution effects on lung-function growth in Hispanic white and non-Hispanic white children and in children with asthma and children without asthma. Although the magnitude of the nitrogen dioxide effect on 4-year growth in FEV_1 and FVC was nearly twice as large in

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

children with asthma, as compared with children without asthma, the difference was not significant for either lung-function measure. Pollution-effect estimates were of a magnitude similar to those in the base model when the sample was restricted to children with complete 4-year follow-up data. Sensitivity analyses of the other pollutants yielded results similar to those for nitrogen dioxide (data not shown). We found no significant association between growth in height and change in pollution during the study period (Table S5 in the Supplementary Appendix), which indicates that our findings on lung-function growth are probably not the result of a secular trend in general development.

The large improvements in lung function associated with reduced air pollution (Table 1) suggest that the mean attained FEV_1 and FVC values at 15 years of age were substantially larger in cohort E (the cohort with the lowest level of exposure, as seen in Fig. 1) than in cohorts C and D. Further analysis of lung function at 15 years of age also revealed significant differences across cohorts in the proportion of children with low lung function (Fig. 3). For example, at a cutoff of 80% for the ratio of observed to predicted values, the proportion of children with low FEV_1 was 7.9% in cohort C, 6.3% in cohort D, and only 3.6% in cohort E ($P<0.005$). Similar significant trends were observed for FVC.

DISCUSSION

This study shows an association between secular improvements in air quality in southern California and measurable improvements in lung-function development in children. Improved lung function was most strongly associated with lower levels of particulate pollution ($PM_{2.5}$ and PM_{10}) and nitrogen dioxide. These associations were observed in boys and girls, Hispanic white and non-Hispanic white children, and children with asthma and children without asthma, which suggests that all children have the potential to benefit from improvements in air quality.

In addition to improvements in lung-function development from 11 to 15 years of age, we also found a strong association between a reduction in air pollution and a reduction in the proportion of children with clinically low FEV_1 and FVC at 15 years of age. In general, the age range of 11 to 15 years captures a period during which lungs are developing rapidly in both boys and girls. Lung-function development continues in girls until their late teens and in boys until their early 20s, but at a much-reduced rate as compared with the rate during the earlier adolescent period.[15,16] It is therefore likely that the improved function we observed in the children who were less exposed to the pollutants will persist into their adulthood. A higher level of lung function in early adulthood may decrease the risk of respiratory conditions.[17] However, the greatest benefit of improvements in lung-function development may occur later in life, because it has been shown that greater lung function in adulthood can contribute to lower risks of premature death and other adverse health outcomes.[18–24] Consistent with the growth effects we have observed in children, there is evidence that reduced exposure to pollution in adulthood can slow the decline in lung function[25] and increase life expectancy.[26,27]

In southern California, motor vehicles are a primary source of $PM_{2.5}$, PM_{10}, and nitrogen dioxide, through direct tailpipe emissions as well as downwind physical and photochemical

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

reactions of vehicular emissions.[28,29] Gasoline-powered and diesel-powered engines contribute to high levels of these pollutants, and improved emission standards for both types of vehicles have contributed to the observed declines in air pollutants. Control strategies implemented in the 1970s and 1980s focused primarily on reducing the levels of ozone, a pollutant with a long history of demonstrated acute health effects.[30] Although levels of ozone continued to decline in the 1990s and 2000s, the changes were smaller than for nitrogen dioxide and particulate matter, and we did not observe ozone-related effects on lung-function growth. This finding is consistent with our previous report that decreased lung-function growth was related to increased exposure to nitrogen dioxide and particulate matter but not to ozone.[6] Only a few other studies have addressed the long-term effects of ozone on lung function in children, and the results have been inconsistent. [31] Because of high correlations among reductions of $PM_{2.5}$, PM_{10}, and nitrogen dioxide (Table S6 in the Supplementary Appendix), we could not assess the independent associations between lung function and each of these pollutants. Many other studies have also been unable to identify the health effects of specific pollutants that are constituents of a multipollutant mixture.[3,32] However, the results of our investigation make it clear that broad-based efforts to improve general air quality are associated with substantial and measurable public health benefits.

A main directive of the 1970 U.S. Clean Air Act was to establish "…ambient air quality standards … allowing an adequate margin of safety … requisite to protect the public health …." A basic tenet of the act is that changes in airborne pollutant levels can lead to improved public health and that the scientific evidence needed to determine the appropriate levels for those standards can be identified. Our observation of improvements in air quality and subsequent improvements in longitudinal respiratory health outcomes may provide objective evidence in support of that basic tenet.

The data necessary to conduct this study were collected over a period of nearly two decades. Strengths of the study include the use of consistent protocols for collecting health, covariate, and air-quality data over the entire study period. Although the extended follow-up period can be viewed as a strength, it also presented several challenges. A change in spirometers during the course of the study was necessary to replace aging equipment and raises the issue of instrumental comparability. To address this, we conducted an additional analysis to show that our findings are robust to the use of different spirometers (Table S7 in the Supplementary Appendix).

The change from annual testing in cohorts C and D to testing every other year in cohort E, as a result of budgetary constraints, may raise concern about dropout of participants in cohort E. In general, bias can occur in a cohort study if dropout depends simultaneously on both outcome and exposure. In our study, however, participant attrition during the follow-up period was not jointly associated with baseline lung function and several measures of exposure, including cohort membership and cohort-specific mean levels of nitrogen dioxide and particulate matter, the pollutants that showed significant associations with lung-function growth. In addition, the magnitude and significance of our observed growth effects were similar among participants with complete follow-up (Table S4 in the Supplementary Appendix), making it unlikely that selective dropout is responsible for our observed associations.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The shift in ethnic background across cohorts to a more Hispanic population, synchronous with general trends occurring more broadly in southern California,[33,34] raises potential concerns about confounding by factors specific to ethnic background. Also, because this is an observational study, it is possible that one or more additional factors associated with both lung-function growth and change in air quality over time could confound our pollution analyses. However, we conducted many sensitivity analyses and found that none of these factors appreciably affected our estimates or inferences. Furthermore, because the mean growth in height from 11 to 15 years of age did not vary over the study period, one might conclude that the change in growth is specific to the lung, with improvement in air quality serving as an important contributing factor.

Another limitation of our study is the lack of a pure "control" community — that is, a community in which there was no change in pollution during the study period. However, we studied five different communities with differing magnitudes of improvement in air quality, which collectively serve as five replicate experiments of our within-community temporal-trend experiment. We conducted an additional analysis that showed that the expected gain in lung function over time within any one community was aligned with the magnitude of improvement in air quality within that community (Fig. S5 in the Supplementary Appendix). The trends in these effects suggest that if we had had a pure control community, we would have seen little change in lung-function growth. This analysis also suggests that even modest improvements in air quality can lead to improved health, although with only five communities included in the study, we caution that we do not have adequate data to make definitive conclusions about the exposure–response relationship.

We have shown that improved air quality in southern California is associated with statistically and clinically significant improvements in childhood lung-function growth. The pollutants we found to be associated with lung-function growth — nitrogen dioxide, $PM_{2.5}$, and PM_{10} — are products of primary fuel combustion and are likely to be at increased levels in most urban environments. These pollutants were among those effectively reduced through targeted policy strategies. If we make the not-unreasonable assumption of causality, the magnitude of the effects we observed and the importance of lung function over the course of the human lifetime justify the efforts that have been made to improve air quality.

Estimated Differences in 4-Year Lung-Function Growth for Median Decreases in Ambient Pollutant Levels.*

Lung-Function Measurement and Pollutant	Lung-Function Difference at 11 Years of Age		Lung-Function Difference at 15 Years of Age		Growth from 11 to 15 Years of Age	
	Mean (95% CI)	P Value	Mean (95% CI)	P Value	Mean (95% CI)	P Value
	ml		*ml*		*ml*	
FEV_1						
Nitrogen dioxide	119.2 (76.5 to 161.9)	<0.001	210.6 (156.0 to 265.2)	<0.001	91.4 (47.9 to 134.9)	<0.001
Ozone	15.0 (−38.5 to 68.6)	0.58	8.3 (−82.9 to 99.6)	0.86	−6.7 (−51.0 to 37.5)	0.77
PM_{10}	87.7 (50.2 to 125.2)	<0.001	153.2 (97.7 to 208.6)	<0.001	65.5 (27.2 to 103.7)	<0.001
$PM_{2.5}$	100.0 (58.9 to 141.2)	<0.001	165.5 (95.4 to 235.6)	<0.001	65.5 (17.1 to 113.8)	0.008
FVC						
Nitrogen dioxide	131.3 (91.0 to 171.6)	<0.001	300.2 (240.0 to 360.3)	<0.001	168.9 (127.0 to 210.7)	<0.001
Ozone	7.6 (−50.2 to 65.4)	0.80	0.3 (−126.0 to 126.5)	0.99	−7.3 (−79.3 to 64.6)	0.84
PM_{10}	93.8 (54.0 to 133.6)	<0.001	206.8 (124.6 to 289.1)	<0.001	113.0 (60.0 to 166.1)	<0.001
$PM_{2.5}$	110.1 (69.8 to 150.4)	<0.001	237.0 (147.2 to 326.7)	<0.001	126.9 (65.7 to 188.1)	<0.001

*The estimated means of community-specific pollution effects on lung-function values at 11 years of age and at 15 years of age and growth from 11 to 15 years of age are scaled to the median of the five community-specific declines in each air pollutant — specifically, 14.1 ppb in nitrogen dioxide, 5.5 ppb in ozone (10 a.m. to 6 p.m.), 8.7 $\mu g/m^3$ in particulate matter with an aerodynamic diameter of less than 10 μm (PM_{10}), and 12.6 $\mu g/m^3$ in particulate matter with an aerodynamic diameter of less than 2.5 μm ($PM_{2.5}$). For example, a decline of 14.1 ppb in nitrogen dioxide is associated with an increase of 91.4 ml in the growth of FEV_1 from 11 to 15 years of age (the mean of the five community- specific slopes).

Effect of exposure to traffic on lung development from 10 to 18 years of age: a cohort study

W James Gauderman, Hita Vora, Rob McConnell, Kiros Berhane, Frank Gilliland, Duncan Thomas, Fred Lurmann, Edward Avol, Nino Kunzli, Michael Jerrett, John Peters

Summary

Background **Whether local exposure to major roadways adversely affects lung-function growth during the period of rapid lung development that takes place between 10 and 18 years of age is unknown. This study investigated the association between residential exposure to traffic and 8-year lung-function growth.**

Methods **In this prospective study, 3677 children (mean age 10 years [SD 0·44]) participated from 12 southern California communities that represent a wide range in regional air quality. Children were followed up for 8 years, with yearly lung-function measurements recorded. For each child, we identified several indicators of residential exposure to traffic from large roads. Regression analysis was used to establish whether 8-year growth in lung function was associated with local traffic exposure, and whether local traffic effects were independent of regional air quality.**

Findings **Children who lived within 500 m of a freeway (motorway) had substantial deficits in 8-year growth of forced expiratory volume in 1 s (FEV_1, –81 mL, p=0·01 [95% CI –143 to –18]) and maximum midexpiratory flow rate (MMEF, –127 mL/s, p=0·03 [–243 to –11), compared with children who lived at least 1500 m from a freeway. Joint models showed that both local exposure to freeways and regional air pollution had detrimental, and independent, effects on lung-function growth. Pronounced deficits in attained lung function at age 18 years were recorded for those living within 500 m of a freeway, with mean percent-predicted 97·0% for FEV_1 (p=0·013, relative to >1500 m [95% CI 94·6–99·4]) and 93·4% for MMEF (p=0·006 [95% CI 89·1–97·7]).**

Interpretation **Local exposure to traffic on a freeway has adverse effects on children's lung development, which are independent of regional air quality, and which could result in important deficits in attained lung function in later life.**

Introduction

Both cross-sectional[1–9] and longitudinal[10–15] studies have shown that lung function in children is adversely affected by exposure to urban, regional air pollution. Evidence has emerged that local exposure to traffic is related to adverse respiratory effects in children, including increased rates of asthma and other respiratory diseases.[16–28] Cross-sectional studies in Europe have shown that deficits in lung function are related to residential exposure to traffic.[27,29–32] However, does traffic exposure have an adverse effect on lung-function development in children? The answer to this question is important in view of the extent of traffic exposure in urban environments and the established relation between diminished lung function in adulthood and morbidity and mortality.[33–39]

We investigated the association between residential exposure to traffic and 8-year lung-function development on the basis of cohort data from the Children's Health Study. We also studied the joint effects of local traffic exposure and regional air quality on children's lung development.

Methods

Participants

The Children's Health Study recruited two cohorts of fourth-grade children (mean age 10 years [SD 0·44], one in 1993 (cohort 1, n=1718) and the other in 1996 (cohort 2, n=1959). All children were recruited from schools in 12 southern California communities as part of an investigation into the long-term effects of air pollution on children's respiratory health.[7,14,40] A consistent protocol was used in all communities to identify schools, and all students targeted for study were invited to participate.[40] Overall, 82% (3677) of available students agreed to participate. Pulmonary-function data were obtained yearly by trained field technicians, who travelled to study schools to undertake maximum effort spirometry on the children, using the same equipment and testing protocol throughout the study period. Details of the testing protocol have been previously reported.[7,15] Children in both cohorts were followed up for 8 years.

A baseline questionnaire, completed at study entry by each child's parent or legal guardian, was used to obtain information on race, Hispanic ethnic origin, parental income and education, history of doctor-diagnosed asthma, in-utero exposure to maternal smoking, and household exposure to gas stoves, pets, and environmental tobacco smoke.[40] A yearly questionnaire, with similar structure to that of the baseline questionnaire, was used to update information on asthma status, personal smoking, and exposure to environmental tobacco smoke. For statistical modelling, a three-category socioeconomic status variable was created on the basis of total household income and education of the parent or guardian who completed the questionnaire. High socioeconomic status (23% of children, n=823) was defined as a parental

income greater than US$100 000 per year, or an income over US$15 000 per year and at least 4 years of college education. The middle category (36%, n=1283) included children with a parental income between US$15 000 and US$100 000 and some (less than 4 years) college or technical school education, and low socioeconomic status (41%, n=1483) included all remaining children.

The study protocol was approved by the institutional review board for human studies at the University of Southern California, and written consent was provided by a parent or legal guardian for every study participant.

Exposure data

We characterised exposure of every study participant to traffic-related pollutants by two types of measures—proximity of the child's residence to the nearest freeway or to the nearest major non-freeway road, and model-based estimates of traffic-related air pollution at the residence, derived from dispersion models that incorporated distance to roadways, vehicle counts, vehicle emission rates, and meteorological conditions.[41] Regional air pollution was continuously monitored at one central site location within each study community over the course of the investigation. Further details of exposure assessment are available in the webappendix.

See Online for webappendix

Statistical methods

The outcome data consisted of 22 686 pulmonary-function tests recorded from 3677 participants during 8 years in both cohorts. We focused on three pulmonary-function measures: forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1), and maximum midexpiratory flow rate (MMEF, also known as FEF_{25-75}). The exposures of primary interest were the traffic measures described above.

We used a hierarchical mixed-effects model to relate 8-year growth in each lung-function measure to traffic exposure, with basic structure that has been previously described.[42] To account for the growth pattern in lung function during this period, we used a linear spline model,[43] constructed so that 8-year growth in lung function was estimated jointly with other model parameters. We estimated and tested the effect of traffic exposure on 8-year growth, and in some analyses on mean lung function at 10 and 18 years of age. The model allowed for separate growth curves for each sex, race, ethnic origin, cohort, and baseline-asthma subgroup. The model also included adjustments for height, height squared, body-mass index (BMI), BMI squared, present asthma status, exercise or respiratory illness on the day of the test, any tobacco smoking by the child in the previous year, and indicator variables for field technician. Random effects for the intercept and 8-year growth parameters were included at the level of participant and community.

To keep the potential effect of outliers to a minimum and to examine possible non-linear exposure-response relations, we used categorical forms of each traffic indicator in our models. For distance to the freeway, we formed four categories—less than 500 m, 500–1000 m, 1000–1500 m, and more than 1500 m. Distances to non-freeway major roads were similarly categorised based on distances of 75 m, 150 m, and 300 m. Model-based estimates of pollution from freeways and non-freeways were categorised into quartiles on the basis of their respective distributions (see webappendix). The categories for all traffic indicators were fixed before any health analyses were done. Traffic effects are reported as the difference in 8-year growth for each category relative to the least exposed category, so that negative estimates signify reduced lung-function growth with increased exposure.

We also considered joint estimation of traffic effects within the community and pollution between communities, which was based on the long-term average pollutant concentrations measured at the central sites (see webappendix). Pollutant effects are reported as the difference in 8-year growth in lung function from the least to the most polluted community, with negative differences indicating growth deficits with increased exposure. Possible modification of a traffic effect by community-average ambient pollutant concentration was tested by inclusion of the appropriate interaction term in the model.

To examine attained lung function, we computed percent-predicted lung function for participants who were measured in 12th grade, our last year of follow-up (n=1497, mean age 17·9 years [SD 0·41]). To estimate predicted FEV_1 values, we first fitted a regression model for observed FEV_1 (log transformed) with predictors log height, BMI, BMI squared, sex, asthma status, race or ethnic origin, field technician, and sex-by-log height, sex-by-BMI, sex-by-BMI squared, sex-by-asthma, and sex-by-race or ethnic origin interactions. We calculated predicted FEV_1 on the basis of this model and percent-predicted as observed divided by predicted FEV_1. We used a regression model to calculate the mean percent-predicted value for each category of distance to the freeway, with adjustment for community. To aid in interpretation, we scaled percent-predicted values so that children who lived furthest (>1500 m) from a freeway had a mean of 100%, and we give means for the remaining distance groups relative to this benchmark. Analogous calculations were used to obtain the percent-predicted mean for FVC and MMEF.

Regression procedures in SAS (version 9.0) were used to fit all models. Associations denoted as significant were those with a p value less than 0·05, assuming a two-sided alternative hypothesis.

Role of the funding source

The funding sources of this study had no role in the study design, collection, analysis, or interpretation of data, in the writing of the report, or in the decision to submit the paper for publication. The corresponding

author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Results

An average of 6·2 pulmonary function tests were done per child. There were equal proportions of male and female participants (webtable 1). Most children were of non-Hispanic white or Hispanic ethnic origin. 440 (12%) children lived within 500 m of a freeway, with most of these children residing in six of the 12 communities (webtable 2 and webfigure). Model-based estimates of pollution from a freeway were skewed toward either high or low values within most study communities.

8-year growth in FVC, FEV_1, and MMEF averaged 1512 mL, 1316 mL, and 1402 mL/s, respectively, in girls, and 2808 mL, 2406 mL, and 2476 mL/s, respectively, in boys. Closer residential distance to a freeway was associated with reduced growth in lung function (table 1). In children who lived within 500 m of a freeway, 8-year growth was significantly reduced compared with those who lived at least 1500 m from a freeway. Large deficits in FEV_1 and MMEF growth were also estimated for the two highest-exposure quartiles of model-based pollution from a freeway, although neither deficit was statistically significant. Indicators of traffic from non-freeway roads, including both distance and model-based pollution estimates, were not associated with reduced growth.

The association between FEV_1 growth and distance to a freeway was significant in various sensitivity analyses (table 2). Compared with the results shown in table 1 (base model), distance-effect estimates were larger with additional adjustment for socioeconomic status. Further investigation showed that low socioeconomic status was associated with increased traffic exposure, with mean residential distance to freeways of 1·8 km (SD 1·32), 2·0 km (1·65), and 2·5 km (1·91) for low, middle, and high groups respectively. However, socioeconomic status was not significantly associated with FEV_1 growth, and therefore adjustment for this variable induced only a modest change. Adjustment for indoor sources of air pollution including gas stoves, pets, and exposure to environmental tobacco smoke also resulted in little change in the estimated freeway-distance effects.

Significant distance effects were seen in the subset of children who reported never having had asthma, and in the subset of children who reported no active tobacco smoking. The relation between FEV_1 growth and distance was noticeably larger in boys than in girls, although a test of effect modification by sex was non-significant (p=0·10). Only six of the 12 communities had substantial numbers of children living within 500 m of a freeway. The estimated effects of freeway distance on lung development were more pronounced in these six higher-traffic communities than in the other communities. There was no significant evidence of heterogeneity in the local distance effects in these six communities (data not shown). Furthermore, around 34% (1267) of children moved from their baseline residence during follow-up but remained in one of the 12 study communities and thus continued to participate. If we omitted post-move lung-function measurements from the analysis, the estimated effects of freeway-distance on FEV_1 growth were more pronounced.

*Pollutant effects are the difference in 8–year FEV_1 growth from lowest to highest observed community–average concentration of the pollutant, specifically: per increase of 37·5 ppb ozone (1000–1800 h), 34·6 ppb of nitrogen dioxide, 9·6 ppb of acid vapour, 51·4 μg/m³ of PM_{10}, 22·8 μg/m³ of $PM_{2·5}$, and 1·2 μg/m³ elemental carbon. Distance effects are the difference in 8–year growth relative to those living >1500 m from a freeway. † A test of whether freeway–distance effect is modified by regional concentration of the pollutant. PM_{10}=particulate matter <10 μm aerodynamic diameter, $PM_{2·5}$=particulate matter <2·5 μm aerodynamic diameter.

Table 3: **Joint effect of regional pollution and local distance to a freeway on 8-year FEV_1 growth**

Reduced lung-function growth was independently associated with both freeway distance and with regional air pollution (table 3). Statistically significant joint models of regional pollution with distance to freeway were seen for nitrogen dioxide, acid vapour, elemental carbon, and particulate matter with aerodynamic diameter less than 10 μm and less than 2·5 μm. Ozone was not associated with reduced lung-function growth. There was no significant evidence of effect modification (interaction) of local traffic effects with any of the regional pollutants.

A subset of 1445 children were observed over the full 8 years of the study, from age 10 to 18 years. In this group, we noted significant deficits in 8-year FEV_1 growth and MMEF growth for those who lived within 500 m of a freeway (table 4). At 10 years of age, there was some evidence of reduced lung function for those who lived closer to a freeway than those who did not, although none of the differences between distance categories was statistically significant. However, by 18 years of age, participants who lived closest to a freeway had substantially lower attained FEV_1 and MMEF than those who lived at least 1500 m from a freeway.

These deficits in average FEV_1 and MMEF translated into pronounced deficits in percent-predicted lung function at 18 years of age (figure). There was a trend of lower percent-predicted lung function for children who lived closer to a freeway than for those who lived further away. The effect was most pronounced for those who lived less than 500 m from a freeway, with average percent predicted values of 97·0% (95% CI 94·6–99·4) for FEV_1 (p=0·013 relative to >1500 m) and 93·4% (89·1–97·7) for MMEF (p=0·006).

Discussion

This study shows that residential proximity to freeway traffic is associated with substantial deficits in lung-function development in children. 8-year increases in both FEV_1 and MMEF were smaller for children who lived within 500 m of a freeway, than for those who lived at least 1500 m from a freeway. Freeway effects were seen in subsets of non-asthmatic and non-smoking participants, which is an indication that traffic exposure has adverse effects on otherwise healthy children. Deficits in 8-year growth resulted in lower attained FEV_1 and MMEF at 18 years of age for participants who lived within 500 m of a freeway than for those who lived further away. Since lung development is nearly complete by age 18 years, an individual with a deficit at this time will probably continue to have less than healthy lung function for the remainder of his or her life.

We previously reported an association between community-average pollutant concentrations and 8-year lung-function growth.[15] That result relied on comparisons in communities that had different concentrations of regional air pollution, and implicated many pollutants such as nitrogen dioxide, acid vapour, particulate matter with aerodynamic diameter less than 10 μm and 2·5 μm, and elemental carbon. Our present study builds on that result, and shows that in addition to regional pollution, local exposure to large roadways is associated with diminished lung-function development

in children. We did not find any evidence that traffic effects varied depending on background air quality, which suggests that even in an area with low regional pollution, children living near a major roadway are at increased risk of health effects. Our results also suggest that children who live close to a freeway in a high pollution area experience a combination of adverse developmental effects because of both local and regional pollution.

We noted a larger freeway effect in boys than in girls, although the difference between sexes was not significant. By contrast, a cross-sectional European study[29] reported larger traffic effects on lung function in girls than in boys.[29] Several factors could explain this discrepancy in sex-specific effects between studies, from differences in specific air pollution mixtures and underlying population susceptibilities, to the general difficulty of comparisons between longitudinal and cross-sectional study effect estimates. In general, however, both studies show that lung function in children is adversely affected by exposure to traffic.

The concentrations of several pollutants are raised near major freeways. Daytime concentrations of black carbon, ultrafine particulate, and other exhaust pollutants have been reported to be high, but decline exponentially, within 500 m of a freeway,[44,45] although night-time concentrations of ultrafine particulate remain above background concentrations for distances greater than 500 m from a freeway.[46] Some studies have reported increased traffic pollution, particularly nitrogen dioxide, at distances over 1000 m from a freeway.[16,47–49] Elemental carbon, an indicator of pollution from diesel exhaust, varies with nearby high-traffic roads[47,50,51] but can also be transported across large distances.[52] Diesel exhaust is one of the primary contributors to particulate-matter concentrations in those communities most affected by traffic.[53] A pollutant such as elemental carbon could explain our reported health effects both locally and regionally.

Both regional ambient and ultrafine particulate matter present in high concentration in close proximity to roadways can elicit oxidative and nitrosative stress in the airways, which results in inflammation.[54,55] Kulkarni and co-workers[32] reported that traffic-related particulate matter was correlated with the amount of carbon in the airway macrophages of children, which in turn was associated with reductions in FEV_1, MMEF, and FVC. Chronic airway inflammation could produce our reported deficits in MMEF and FEV_1. Additional research is needed to identify the specific traffic pollutants that bring about health effects, and to elucidate the contribution of each pollutant to regional and local associations.

A strength of this study was the long-term, prospective follow-up of two large cohorts of children, with exposure and outcome data obtained consistently. However, as in any epidemiological study, our results could be confounded by one or more other factors related to both traffic and lung-function growth. Our results were robust

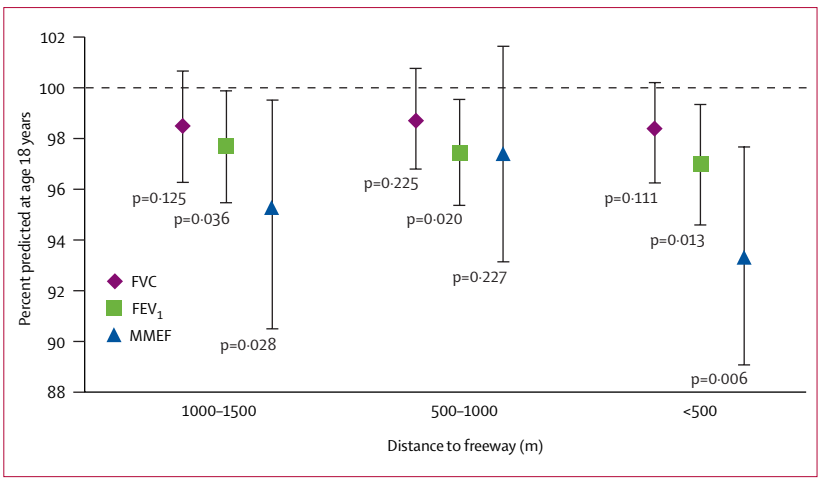

Figure: **Percent-predicted lung function at age 18 years versus residential distance from a freeway**
The horizontal line at 100% corresponds to the referent group, children living >1500 m from a freeway.

to adjustment for several factors, including socioeconomic status and indoor sources of air pollution, but the possibility of confounding by other factors still exists. Throughout the 8-year follow-up, we noted around an 11% loss of study participants per year. Participant attrition is a potential source of bias in cohort studies. We analysed the subset of children who were followed up for the full 8-year duration of the study and also noted significant traffic-effect estimates, which make participant loss an unlikely explanation for our results. We did not note a significant association between growth and model-based pollution from a freeway, despite large estimated deficits in the highest-exposure quartiles (table 1). However, we were restricted in detection of an association with model-based pollution from freeways because there was little variation in this measure within most of our study communities (webtable 2).

We have shown that residential distance from a freeway is associated with significant deficits in 8-year respiratory growth, which result in important deficits in lung function at age 18 years. This study adds to evidence that the present regulatory emphasis on regional air quality might need to be modified to include consideration of local variation in air pollution. In many urban areas, population growth is forcing the construction of housing tracts and schools near to busy roadways, with the result that many children live and attend school in close proximity to major sources of air pollution. In view of the magnitude of the reported effects and the importance of lung function as a determinant of adult morbidity and mortality, reduction of exposure to traffic-related air pollutants could lead to substantial public-health benefits.

[1]Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, California, USA; [2]Department of Environmental Health, School of Public Health, University of California, Berkeley, Berkeley, California, USA; [3]Department of City and Regional Planning, College of Environmental Design, University of California, Berkeley, Berkeley, California, USA; [4]Sonoma Technology, Inc., Petaluma, California, USA

Background: Childhood body mass index (BMI) and obesity prevalence have been associated with exposure to secondhand smoke (SHS), maternal smoking during pregnancy, and vehicular air pollution. There has been little previous study of joint BMI effects of air pollution and tobacco smoke exposure.

Methods: Information on exposure to SHS and maternal smoking during pregnancy was collected on 3,318 participants at enrollment into the Southern California Children's Health Study. At study entry at average age of 10 years, residential near-roadway pollution exposure (NRP) was estimated based on a line source dispersion model accounting for traffic volume, proximity, and meteorology. Lifetime exposure to tobacco smoke was assessed by parent questionnaire. Associations with subsequent BMI growth trajectory based on annual measurements and attained BMI at 18 years of age were assessed using a multilevel modeling strategy.

Results: Maternal smoking during pregnancy was associated with estimated BMI growth over 8-year follow-up (0.72 kg/m^2 higher; 95% CI: 0.14, 1.31) and attained BMI (1.14 kg/m^2 higher; 95% CI: 0.66, 1.62). SHS exposure before enrollment was positively associated with BMI growth (0.81 kg/m^2 higher; 95% CI: 0.36, 1.27) and attained BMI (1.23 kg/m^2 higher; 95% CI: 0.86, 1.61). Growth and attained BMI increased with more smokers in the home. Compared with children without a history of SHS and NRP below the median, attained BMI was 0.80 kg/m^2 higher (95% CI: 0.27, 1.32) with exposure to high NRP without SHS; 0.85 kg/m^2 higher (95% CI: 0.43, 1.28) with low NRP and a history of SHS; and 2.15 kg/m^2 higher (95% CI: 1.52, 2.77) with high NRP and a history of SHS (interaction p-value 0.007). These results suggest a synergistic effect.

Conclusions: Our findings strengthen emerging evidence that exposure to tobacco smoke and NRP contribute to development of childhood obesity and suggest that combined exposures may have synergistic effects.

Introduction

Prevalence of obesity in U.S. children has been increasing for > 40 years [Centers for Disease Control and Prevention (CDC) 2011]. The current epidemic threatens the health of a generation of children because obesity and increased body mass index (BMI) in childhood are strong determinants of morbidity and premature mortality in adult life (Reilly and Kelly 2011; Tirosh et al. 2011). Beyond dietary factors and physical activity, a growing body of evidence indicates that environmental stressors may play a role in the etiology of childhood obesity (Blumberg et al. 2011).

Maternal smoking during pregnancy (hereafter referred to as *in utero* exposure) predicts subsequent childhood obesity (Ino 2010). *In utero* and secondhand tobacco smoke (SHS) exposure in children are correlated, but a few studies have found BMI, overweight, and obesity to be associated with SHS independent of *in utero* exposure (Griffiths et al. 2010; Raum et al. 2011). There is also emerging evidence that SHS exposure in adults is associated with obesity, as well as other metabolic abnormalities (Xie et al. 2010; Zhang et al. 2011). A recent study suggested that *in utero* exposure to another combustion source, ambient near-roadway pollution (NRP; estimated based on measured maternal exposure to polyaromatic hydrocarbons), is associated with increased BMI and obesity at 7 years of age (Rundle et al. 2012). However, to our knowledge there has been no previous prospective investigation in school children of joint obesogenic effects of tobacco smoke and air pollution exposure. Because these exposures are common, they have potentially significant clinical and public health impact.

The Southern California Children's Health Study (CHS) collected information on *in utero* exposure to maternal smoking, exposure to SHS (before or at the time of enrollment), and exposure to ambient particles and NRP at the time of enrollment in a longitudinal study of BMI growth trajectory across adolescence and attained BMI at 18 years of age (Gauderman et al. 2007; Jerrett et al. 2010). We estimated the independent and joint effects of tobacco smoke and ambient exposure on BMI in the CHS.

Methods

Two cohorts of children in fourth grade classrooms in 12 Southern California communities (Figure 1) were recruited at average age 10 years in 1993 and 1996 and followed through secondary school graduation 8 years later, as described previously (Gauderman et al. 2007; Jerrett et al. 2010). Of the 3,887 participants recruited, 569 (14.6%) had fewer than two BMI measurements, leaving a sample of 3,318 for analysis. Subsequent attrition was 5–10% per year. For analyses including NRP exposure, one community (n = 300 participants) was excluded, as described below.

Height (to the nearest centimeter) and weight (to the nearest pound) were measured at study entry and annually at the child's school by a trained study technician, following a standardized procedure that included daily scale calibration (Jerrett et al. 2010). BMI (weight in kilograms divided by height in

square meters) was calculated at each visit. Overweight and obesity were defined using the CDC criteria of > 85% and < 95%, and ≥ 95%, respectively, of the age- and sex-specific U.S. population distribution (CDC 2013). Participants in the analyses had on average (± SD) 6.4 ± 2.4 BMI measurements.

Parents completed a detailed baseline questionnaire that provided information about each child's *in utero* and SHS exposure and relevant covariates, including physical activity, childhood medical history, and the child's residential location history. Study procedures were approved by the University of Southern California Institutional Review Board, and parents provided written informed consent on behalf of themselves and their children at the time of enrollment of each child into the study.

Information on *in utero* exposure to maternal smoking, the child's history of previous SHS exposure, and number of smokers in the home at study enrollment was provided in the baseline questionnaire. Children were classified as having *in utero* exposure if a parent indicated "yes" in response to the question "Did your child's biologic mother smoke while she was pregnant with your child? (Include time when she was pregnant but did not yet know that she was.)" Any SHS exposure before study entry was classified based on a positive response to either of the following questions: "Does anyone living in this child's home currently smoke cigarettes, cigars or pipes on a daily basis INSIDE THE HOME?" or "In the past, has anyone living in this child's home ever smoked cigarettes on a daily basis INSIDE THE HOME while the child was living there?" For children exposed to SHS at home at study entry, the number of smokers was characterized by the question "How many people smoke inside this child's home on a daily basis?" Responses were categorized as 0, 1, 2, or more smokers. Children who indicated that they had smoked > 6 cigarettes in the last week were classified as smokers.

Near-roadway air pollution exposure. Data on traffic proximity, volume, Southern California vehicular fleet emissions, and meteorology were used to characterize exposure at each child's primary residential address at study entry. Participant residence and school addresses were standardized and their locations were geocoded to 13 m perpendicular to the side of the adjacent road, using the Tele Atlas database and software (http://www.na.teleatlas.com). Distance to the nearest major road was estimated using ESRI ArcGIS version 8.3 (http://www.esri.com). We included in the analysis only children with residential addresses for which the TeleAtlas geocoding software assigned its highest quality match code. These addresses were located on the correct side of the street, with their relative position between cross streets determined by linear interpolation of residence number between the nearest intersections. One of the original 12 CHS communities, Lake Arrowhead, was not included in analyses of NRP. Many participants in this community had only a post office box rather than a street address. Lake Arrowhead also has winding streets and long distances between intersections that made it difficult to interpolate accurately to a geocoded location.

Annual average daily traffic volumes on roadways were obtained from the California Department of Transportation Highway Performance Monitoring System (2005). Using previously described methods, we transferred the traffic volumes from the Department of Transportation roadway network to the TeleAtlas networks (Wu et al. 2005). Annual average exposure to local NRP at homes and schools was estimated from CALINE4 dispersion models that incorporate distance to roadways, vehicle counts, vehicle emission rates, wind speed and direction, and height of the mixing layer in each community (Benson 1992). Separate estimates were made for the contribution of traffic on all other roadways to concentrations of several pollutants, including carbon monoxide, nitrogen dioxide, total oxides of nitrogen (NO_x), elemental and organic carbon, and particulate matter ≤ 10 μm (PM_{10}) and ≤ 2.5 μm in aerodynamic diameter ($PM_{2.5}$) These estimated pollutant exposures should be regarded as indicators of incremental increases due to primary emissions from local vehicular traffic on top of background ambient levels, based on annual average estimates. For our analysis, we characterized NRP exposure using modeled NO_x to represent the incremental contribution of local traffic to a more homogeneous community background concentration of NO_x that included both primary and secondary pollution resulting from long range transport and regional atmospheric photochemistry. This metric was highly correlated with other pollutants estimated by CALINE4 (R > 0.95). Therefore, modeled NO_x represented primary local NO_x from vehicular traffic, these other highly correlated pollutants in fresh traffic exhaust, and probably other pollutants for which we did not estimate exposures. The mean (± SD) NRP was 6.9 ± 7.5 (expressed as parts per billion of the near-roadway contribution to NO_x), median 3.86 ppb. Associations with BMI were estimated for a 16.8-ppb increase in NRP, which represented the difference between the 90th and 10th percentiles of the overall distribution (17.8 and 1.0 ppb, respectively). Associations with quartiles of NRP exposure (< 1.85, 1.85–3.86, 3.86–9.08, and > 9.08 ppb) were also examined. In models of joint effects with SHS and *in utero* exposure, NRP was also treated as a dichotomous variable stratified at the study population median.

Covariates. We included child's ethnicity and age, as reported by the parent on the baseline questionnaire at study entry, sex, community, and year of enrollment (1993 or 1996) in all models. In addition, we examined potential confounding by

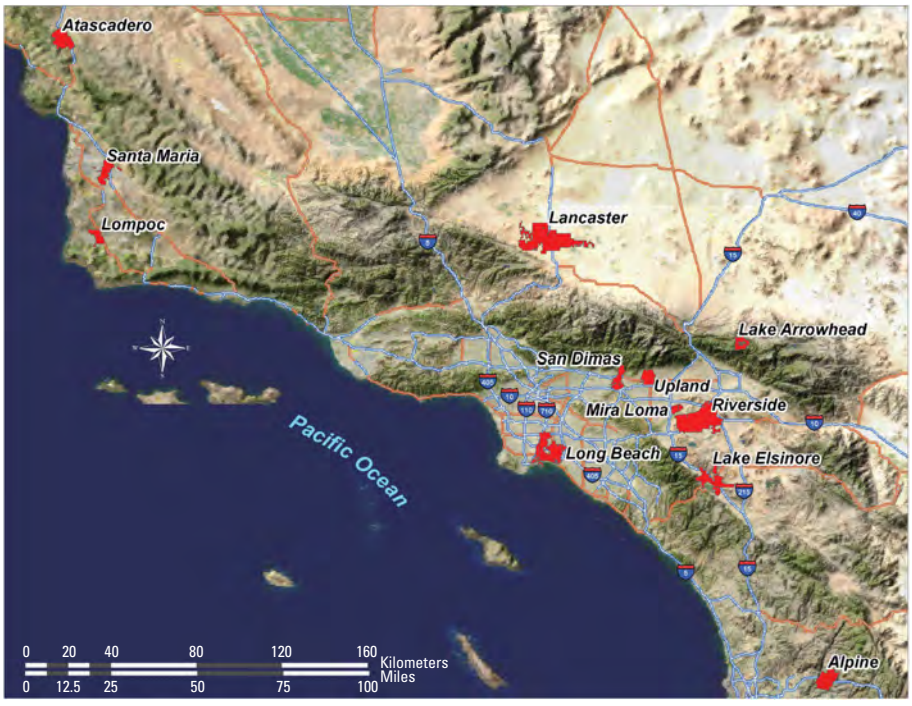

Figure 1. Southern California Children's Health Study communities.

individual, household level, and neighborhood confounders of effects on BMI in this population, as described previously (Jerrett et al. 2010; Wolch et al. 2011). Information on child's history of asthma and physical activity were based on information collected at study entry, including the number of team sports in which the child participated. Social characteristics of the child, family, and neighborhood included whether the child was born outside of the United States and had health insurance coverage at study entry, the educational attainment and responding parent preference for a Spanish questionnaire, neighborhood population density within 500 m of the child's home, and residential census block unemployment among men and women and percentage living in poverty. Using information available from publicly and commercially available data sets, features of the built environment were obtained, including walkability based on street connectivity, acres of parks and recreation facilities, green space based on the Normalized Difference Vegetation Index (NDVI), and a restaurant or store selling food, all based on a 500-m Euclidian buffer around the child's residence at study entry, using previously described methods (Jerrett et al. 2010; Wolch et al. 2011). Rates of violent crime in each study community were characterized, also as previously described (Jerrett et al. 2010; Shankardass et al. 2011; Wolch et al. 2011).

Information on annual average regional pollutant exposure to PM_{10} and $PM_{2.5}$ mass, to nitrogen dioxide and to ozone from 1000 hours to 1800 hours was available from continuous measurements made at a central-site monitor in each community throughout the period of follow-up of this cohort. We have previously shown that there was relatively little temporal variation in the annual exposure to these pollutants in each community (Gauderman et al. 2004). Therefore, we used an 8-year annual average exposure to each regional pollutant for analyses.

Statistical analysis. We used a multilevel approach to estimate associations with BMI growth (i.e., the projected change in BMI) over an 8-year follow-up period while explicitly controlling for baseline BMI and for differences in the progression of BMI by age and sex. Sex-specific BMI trajectories were estimated using linear splines with knots at 12, 14, and 16 years of age to account for nonlinearity in BMI change, with random effects on all growth parameters to account for subject-to-subject heterogeneity in BMI trajectories. Models were parameterized to estimate associations of tobacco smoke and NRP with attained BMI at 18 years, in addition to associations with overall BMI growth over the follow-up period, and effects were estimated at various levels: between years, between individuals, and between communities.

The modeling approach is similar to what has been previously described (Berhane and Molitor 2008; Jerrett et al. 2010), but it includes a richer random-effects structure on all growth curve parameters for better control of subject-to-subject heterogeneity than we have previously used in analysis of this data set (Jerrett et al. 2010). We began by fitting a base model that included ethnicity, race, sex, year of enrollment, and community, with a missing indicator category used to account for missing values for potential confounders. Each potential confounder was examined to see whether it changed the coefficient of tobacco smoke or NRP exposure by at least 10% when added to the model. A missing indicator category was included for missing values for potential confounders. We also included a fixed or random effect for community, as appropriate. Because some regional pollutant concentrations were correlated with the community mean NRP exposure, NRP was deviated from its community mean to produce orthogonal exposures in models that also included regional pollution.

Because BMI trajectories during childhood are different for boys and girls, interaction terms were included in the final models, and Wald tests were used to assess whether effects of tobacco smoke and NRP exposure on BMI growth and attained level were different in boys and girls. Because they were not different, associations were reported for both sexes combined for parsimony. In addition, we modeled interactions between tobacco smoke and NRP exposures. In sensitivity analyses, we modeled the joint effects of NRP and SHS centered at each age of follow-up among 1,514 children at the same address for at least 4 years at study entry, to estimate associations with attained BMI in children with prolonged exposure to a consistent NRP environment before study enrollment.

Statistical significance was based on a probability of 0.05 for a two-sided hypothesis. Data were analyzed using SAS (version 9.2; SAS Institute Inc., Cary, NC) and R (version 3.0.1; R Foundation for Statistical Computing, Vienna, Austria) software. Data were compiled using ArcGIS 9.2, and some distance measurements were computed using Matlab version R2006a (Mathworks, Natick, MA).

Results

The mean age of children at study entry in 1993 and 1996 in two waves of recruitment was 10.1 years (SD 0.59). Over the 8 years of follow-up from enrollment through year 8 (average age, 18 years), there was a 5.3-unit increase in mean BMI, from 18.3 ± 3.4 to 23.6 ± 5.1. The prevalence of obesity increased from 12% to 13.3% during this period.

Most children were non-Hispanic white or Hispanic (Table 1). Average BMI at baseline varied from 17.6 (± 2.9) kg/m^2 among Asians to 19.1 (± 3.9) in Hispanics in this unadjusted analysis. A larger proportion of children had a history of SHS exposure (34.6%) at enrollment than of *in utero* exposure (16.7%). A history of exposure to SHS was associated with small increased BMI (18.5 ± 3.5 kg/m^2) compared with children with no exposure (18.2 ± 3.4 kg/m^2). Seven children reported personal smoking at study entry. Average BMI by quartile of NRP

Table 1. Selected participant characteristics and exposures at Children's Health Study enrollment.

Characteristic	No. (%)[a]	BMI (mean ± SD)
Race/ethnicity		
African American	155 (4.7)	18.7 ± 3.5
Asian	151 (4.5)	17.6 ± 2.9
Hispanic white	1,000 (30.1)	19.1 ± 3.9
Non-Hispanic white	1,825 (55.0)	18.0 ± 3.1
Other	187 (5.6)	18.3 ± 3.9
Sex		
Male	1,647 (49.6)	18.4 ± 3.5
Female	1,671 (50.4)	18.3 ± 3.5
SHS at study entry		
No one ever smoked in the house	2,070 (65.4)	18.2 ± 3.4
Anyone ever smoked in the house	1,094 (34.6)	18.5 ± 3.5
In utero exposure to maternal smoking		
No	2,764 (83.2)	18.3 ± 3.5
Yes	554 (16.7)	18.6 ± 3.6
Personal smoking		
No	3,311 (99.8)	18.4 ± 3.5
Yes	7 (0.21)	20.3 ± 4.7
NRP exposure[b]		
Lowest quartile (< 1.85)	736	18.1 ± 3.2
Second quartile (1.85–3.86)	736	18.7 ± 3.6
Third quartile (> 3.86–9.08)	736	18.2 ± 3.5
Fourth quartile (> 9.08)	736	18.5 ± 3.8

[a]For the first observation of the participant (n = 3,318); denominator (n = 3,318) varies due to missing covariates values.
[b]In parts per billion NO_x; 11 communities.

ranged from 18.1 ± 3.2 kg/m^2 for the lowest quartile to 18.7 ± 3.6 kg/m^2 for the second quartile, without evidence for a dose–response relationship. In addition, BMI was higher in children with asthma and in children who were foreign born, did not play a team sport, and who had a responding parent with less than a high school education or who completed a Spanish questionnaire (see Supplemental Material, Table S1).

Maternal smoking during pregnancy, a history of SHS exposure, and NRP exposure at the child's home at study entry were each associated both with the estimated 8-year growth of BMI and with estimated attained BMI at 18 years (Table 2). Compared with children who had no history of SHS exposure at enrollment, those with SHS exposure had a greater estimated increase in BMI from baseline to age 18 years [0.81 kg/m^2; 95% confidence interval (CI): 0.36, 1.27] and a higher attained BMI at age 18 (1.23 kg/m^2 higher on average; 95% CI: 0.86, 1.61), consistent with a greater rate of increase during follow up combined with a higher average BMI at study entry. Number of smokers in the home at study entry was also associated with increased 8-year growth trajectory (0.48 kg/m^2; 95% CI: 0.16, 1.12 for one smoker, 1.08 kg/m^2; 95% CI: 0.19, 1.97 for two or more smokers) and with increased attained BMI at 18 years (0.95 kg/m^2; 95% CI: 0.42, 1.47 for one smoker, 1.77 kg/m^2; 95% CI: 1.04, 2.51 for two or more smokers). Associations of *in utero* exposure to maternal smoking (vs. no *in utero* exposure) with BMI growth (0.72 kg/m^2 higher; 95% CI: 0.14, 1.31) and attained BMI at 18 years (1.14 kg/m^2 higher; 95% CI: 0.66, 1.62) were similar in magnitude to associations of SHS with BMI. There was no evidence of an association between personal smoking at study entry with BMI growth (–0.33 kg/m^2; 95% CI: –0.66, 1.61) and with attained level (–0.15 kg/m^2; 95% CI: –0.40, 0.15), not tabulated. A 16.8-ppb increase in NRP (representing an increase from the 10th to the 90th percentile of the exposure distribution) also was associated with 8-year growth in BMI (1.13 kg/m^2 higher; 95% CI: 0.61, 1.65) and attained BMI (1.27 kg/m^2 higher; 95% CI: 0.75, 1.80; Table 2). When NRP exposure was categorized into quartiles, the association with BMI growth was 1.10 (95% CI: 0.46, 1.74), 1.26 (95% CI: 0.6, 1.91), and 2.31 (95% CI: 1.66, 2.96) kg/m^2 for the 2nd, 3rd, and 4th quartile compared with the growth in children in the 1st quartile of exposure; attained BMI at 18 years was 1.63 (95% CI: 1.08, 2.18), 1.68 (95% CI: 1.08, 2.28), and 2.29 (95% CI: 1.57, 3.01) kg/m^2 higher than in children in the 1st quartile of exposure (results not tabulated).

In a model mutually adjusted for SHS and *in utero* exposure, the associations of each with BMI growth and attained BMI at age 18 were attenuated but remained significant, except for the adjusted effect estimate for *in utero* exposure on growth (0.35 kg/m^2: 95% CI: –0.29, 0.99). (See Supplemental Material, Table S2.) However, SHS and *in utero* exposure to maternal smoking were correlated (phi coefficient 0.45).

There was no confounding (based on a change > 10% of the estimate in Table 2) of the associations of attained BMI at 18 years or of BMI growth with NRP, SHS, or *in utero* exposure to maternal smoking by team sports participation or history of asthma; by social characteristics of the child, family, or neighborhood, including whether the child was foreign born, parental education, language of questionnaire, residential population density, and residential census tract rates of unemployment; or by features of the built environment including neighborhood walkability, availability of sports and recreation facilities, and green cover. The effect of NRP was not confounded by community regional average PM_{10}, $PM_{2.5}$, ozone, or nitrogen dioxide levels (nor in these models were there statistically significant associations of any regional pollutant with BMI growth or attained level at 18 years of age; data not shown). However, there were modest changes in the estimates in Table 2 after adjusting for percent poverty in residential census tract, including increased effect of SHS (by 15%) on BMI growth to 0.93 kg/m^2 (95% CI: 0.50, 1.36). Effect of NRP on growth was increased (by 12%) to 1.26 kg/m^2 (95% CI: 0.62, 1.91). The effect of NRP on attained BMI level was reduced in models adjusted for availability of health insurance for the child (by 10%) to 1.14 kg/m^2 (95% CI: 0.69, 1.59) and for a restaurant or food store within 500 m of the home (by 18%) to 1.04 kg/m^2 (95% CI: 0.51, 1.56). In an analysis adjusting for a common set of these confounders across all models, associations of SHS exposure with BMI growth and attained BMI at 18 years of age were not substantially changed (see Supplemental Material, Table S3). There was modest attenuation of associations of NRP with BMI growth (from 1.13 kg/m^2; 95% CI: 0.61, 1.65 to 0.99 kg/m^2; 95% CI: 0.46, 1.51) and with attained BMI (from 1.27 kg/m^2; 95% CI: 0.75, 1.80 to 1.10 kg/m^2; 95% CI: 0.58, 1.61).

We also found no significant differences between boys and girls in the associations of tobacco smoke and NRP exposures with BMI growth or attained level, based on tests for interaction (data not shown).

We found evidence of synergism between tobacco smoke and NRP exposure on attained BMI at 18 years of age (Table 3). Compared with attained BMI among participants living in residences with low exposure to NRP with no history of SHS exposure, being in the upper half of the NRP exposure distribution (without a history of SHS) or having a history of SHS exposure (with low NRP) was associated with attained BMI estimates that were 0.80 kg/m^2 higher (95% CI: 0.27, 1.32) and 0.85 kg/m^2 higher (95% CI: 0.43, 1.28), respectively. Attained BMI among participants with both high NRP residences and a history of SHS exposure was 2.15 kg/m^2 higher (95% CI: 1.52, 2.77) in contrast with an expected increase (based on the sum of the individual effect estimates) of 1.65 kg/m^2 (interaction p-value = 0.007). There were no significant interactions of

Table 2. Association of sources of tobacco smoke and NRP exposures[a] at study enrollment with BMI growth over 8 years and with attained BMI at 18 years of age.

Exposure	BMI growth[b] (95% CI)	Difference in attained BMI[b] (95% CI)
SHS[c]	0.81 (0.36, 1.27)*	1.23 (0.86, 1.61)*
1 smoker in home	0.48 (0.16, 1.12)	0.95 (0.42, 1.47)
≥ 2 smokers in home	1.08 (0.19, 1.97)	1.77 (1.04, 2.51)
Maternal smoking during pregnancy[c]	0.72 (0.14, 1.31)	1.14 (0.66, 1.62)*
NRP[c]	1.13 (0.61, 1.65)*	1.27 (0.75, 1.80)*

[a]Exposure before or at enrollment at average age 10 years. [b]BMI growth (kg/m^2) over 8-year follow-up, and difference in attained BMI at age 18 years, compared with participants without tobacco smoke exposure, or scaled to NRP 10th–90th percentile range of 16.8 ppb of NO_x, adjusted for ethnicity, sex, community, year of enrollment, and age; NRP exposure restricted to 11 communities. [c]For SHS, n = 3,164; for maternal smoking during pregnancy, n = 3,318; for NRP, n = 2,944. *$p < 0.001$.

Table 3. Synergistic effects of SHS and NRP exposures[a] on attained BMI at age 18 years.

SHS	NRP exposure	Difference in attained BMI[b] (95% CI)
No	Low	Reference
No	High	0.80 (0.27, 1.32)*
Yes	Low	0.85 (0.43, 1.28)**
Yes	High	2.15 (1.52, 2.77)**

[a]Exposure before or at enrollment at average age 10 years (n = 2,806 with complete information on both exposures); NRP (11 communities) dichotomized at population median of NRP (3.86 ppb NO_x). [b]Difference in attained BMI (kg/m^2) at age 18 years, compared with participants without SHS exposure and with low residential NRP exposure, adjusted for ethnicity, community, sex, year of enrollment, child health insurance, percent poverty in the census block, and no food outlet within 500-m road network residence buffer; analysis restricted to 11 communities. *$p < 0.01$. **$p < 0.001$.

in utero exposure to maternal smoking with either NRP or SHS for BMI growth or attained level (data not shown).

A sensitivity analysis was restricted to the 1,514 participants living at the same address for at least 4 years before study entry in order to determine whether effects would be larger in children with consistent longer-term NRP exposures. For this analysis the association of each exposure category with mean attained BMI was compared with BMI among referent children with neither SHS nor high residential NRP exposure (represented by zero on the *x*-axis in Figure 2). To illustrate the pattern of estimated effect on attained BMI the model-based estimate was re-centered at each age of follow-up. The association of attained BMI at 18 years with NRP with early-life SHS exposure was larger than that observed in the entire population (in Table 3), and the joint effect estimate accounted for almost an additional 3 kg/m^2, compared with children who had neither exposure.

There was also evidence of an interaction between SHS and NRP based on NO_x modeled as a continuous variable. Specifically, among children with no history of SHS, a 16.8-ppb increase in NO_x was associated with a 0.34-kg/m^2 increase in attained BMI at age 18 years (95% CI: –0.26, 0.94), compared with a 1.22-kg/m^2 increase (95% CI: 0.65, 1.77) among children with a history of SHS (interaction p-value < 0.001).

Discussion

Previous studies have reported associations between SHS and BMI in younger children (Griffiths et al. 2010; Raum et al. 2011). In our study population, both history of SHS exposure at study entry and of *in utero* exposure were associated with greater subsequent BMI growth over an 8-year period spanning adolescence through young adulthood. Furthermore, associations of SHS exposure with BMI attained by the time these children reached adult age were stronger among children exposed to higher levels of NRP. Children with a history of SHS exposure who lived in a home in the upper half of the NRP distribution had BMI at 18 years of age > 2 kg/m^2 larger than BMI in young adults with neither SHS nor high NRP exposures. The prospective design and corresponding temporal sequence of exposure and substantial increases in BMI, which were not explained by a variety of potential confounders, the consistency of association and the synergism between combustion products from two different sources, and the emerging epidemiological and toxicological evidence all suggest that these combustion products contribute to the development of obesity.

Previous work has identified the systemic inflammatory effect of SHS and particulate air pollution as a potential common mechanism explaining the epidemiologic associations with cardiopulmonary disease [Pope and Dockery 2006; U.S. Department of Health and Human Services (DHHS) 2010]. Emerging evidence from experiments on mice suggests that $PM_{2.5}$-induced adipose tissue inflammation and redistribution of adipose tissue to viscera may play a key role in the development of insulin resistance, diabetes, and systemic inflammatory effects (Sun et al. 2009; Zou 2010). However, in these studies metabolic and inflammatory effects of $PM_{2.5}$ were not associated with weight gain. In contrast, a recent experimental study reported that early-life exposure of mice to diesel exhaust particulate, a model NRP, resulted in markedly larger subsequent weight gain than in animals exposed to filtered air (Bolton et al. 2012). Our results showing associations of BMI with NRP but not with regional PM are consistent with these experimental results. Further investigation is needed to understand the mechanisms underlying the NRP mixture effects.

Other biologically plausible explanations for the obesogenic effects of tobacco smoke and NRP include inhibition of catecholamine-induced lipolysis by polycyclic aromatic hydrocarbons (PAHs), resulting in weight gain in experimental animals (in the absence of increased caloric intake) (Irigaray et al. 2006). PAHs are part of the pollutant mixture in both NRP and SHS (DHHS 2010). Nicotine exposure from maternal smoking during pregnancy is a plausible cause of subsequent obesity, based on toxicological studies (Thayer et al. 2012). PM exposure has been reported to cause oxidative stress–mediated damage to mitochondria and down-regulation of expression of key brown adipose tissue genes involved in thermogenesis and energy expenditure (Xu et al. 2011). Direct inflammatory effects on feeding centers in the hypothalamus, or indirect effects through up-regulation of inflammatory pathways in adipose tissue, may also result in increased dietary intake (Bolton et al. 2012).

In utero exposure to tobacco smoke has been consistently reported to have obesogenic effects (Thayer et al. 2012). Our results support a few other studies showing increased BMI and obesity in SHS-exposed children, even after adjustment for *in utero* exposure (Griffiths et al. 2010; Raum et al. 2011). A few other epidemiological studies also have reported associations of markers of NRP exposure with obesity. Early-life exposure to PAHs in children in New York City was associated with the subsequent development of obesity by 7 years of age (Rundle et al. 2012).

We have previously reported associations between traffic density and BMI in this cohort, which we attributed to reduced opportunities for physical activity in an environment with heavy traffic corridors, although reported physical activity did not explain the associations (Jerrett et al. 2010). Exposure assignment to residence in the current analysis accounting for meteorology and vehicular emissions is likely to have been a more accurate estimate of NRP exposure than traffic density alone. Associations of modeled NRP exposure with increased BMI have also been observed in another Children's Health Study cohort (Jerrett et al. 2014).

Maternal smoking and childhood SHS exposures may have been misclassified, although there is evidence from at least some populations that such exposures may be accurately reported by mothers (Gehring et al. 2006; Matt et al. 2000; Pickett et al. 2009). Exposure would have to have been both misclassified and also overreported by parents of children who would go on to have steeper BMI trajectory to explain the observed results. Given the strength of the association and the interaction with NRP, this seems an unlikely explanation for the observed results.

We examined the potential for selection or confounding bias to explain these results. There were 569 participants from the cohort who were not available for at least two measurements of height and weight. Attrition is a potential source of bias in a cohort study if loss to follow-up is related both to exposure and outcome, but BMI outcome at study entry did not differ between those lost to follow-up (18.5 ± 3.6 kg/m^2) and those with two or more BMI measurements contributing to the analysis (18.3 ± 3.4 kg/m^2). Mean exposure to NRP (adjusted for community) differed little between participants and those lost to follow-up (by only 0.013 ppb NO_x). SHS exposure was more common

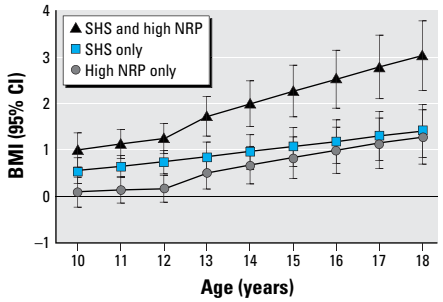

Figure 2. Estimated effects of SHS and NRP exposure on attained BMI at ages 10–18 years among long-term residents (n = 1,514 with ≥ 4 years at same residence at time of enrollment in 11 communities with NRP estimates). Differences in mean BMI (95% CIs) at each age were estimated for children with NRP above the median and no history of SHS (high NRP only), children with a history of SHS and NRP below the median (SHS only), and children with a history of SHS and high NRP, compared with a common reference group of children who had low NRP and no history of SHS at enrollment.

among those lost to follow-up (45%) than in participants contributing to the analysis (35%), as was *in utero* exposure to maternal smoking (23% compared with 17%). Some other sociodemographic characteristics (foreign-born parents, health insurance for the child, race/ethnicity, and parental education) also differed among participants and those lost to follow-up (see Supplemental Material, Table S4). However, we adjusted for these sociodemographic characteristics, for health and physical activity information about the child, and for other features of the urban environment that might affect patterns of activity or food intake, and these did not substantially influence the pattern of associations of SHS and NRP with BMI. For caloric intake to explain our results, it would not only have had to be correlated both with SHS and NRP, but also to explain the synergistic pattern of association of these exposures with BMI, and this seems an unlikely confounding scenario. In addition, we observed significant associations of SHS and NRP with BMI in a subgroup of children who were followed through at least one of the last 2 years of the study (years 7 and 8 of follow-up; n = 2,120), and effect estimates were generally similar to those in the participants as a whole (results not shown). Although selection bias and confounding by other factors cannot be excluded as an explanation for our results, these analyses provide little evidence that this was the case.

The magnitude of the associations of BMI with SHS and NRP was large, especially in combination. The 2 kg/m^2 associated with the combination of SHS with high-NRP exposures at 18 years of age (compared with low NRP and no SHS) were almost half the standard deviation of 5.1. A 2-kg/m^2 relative increase in attained BMI is equivalent to a 6-kg (6.6%) increase in body weight in an adult male who is 1.78 m tall and weighs 95 kg (BMI = 30). For comparison, multifaceted, albeit short-term, interventions in adolescents are estimated to result in weight reductions of < 0.1 kg/m^2 (Waters et al. 2011).

Further research is warranted to determine whether our findings can be replicated in other populations and to assess both the potential contribution of combustion sources to the epidemic of obesity and the potential impact of interventions to reduce exposure. *In utero* and SHS exposure and regional ambient PM exposure have been decreasing in California over the past several decades during which the obesity epidemic has developed (Al-Delaimy et al. 2010), so these exposures by themselves are unlikely to have contributed to the epidemic. However, these trends in regional air pollutants have limited relevance to the potential role of NRP, which is a different pollutant mixture. Vehicle miles traveled, exposure to some components of the NRP mixture, and near-roadway residential development have increased during this period (Geller et al. 2005) (U. S. Department of Transportation, Federal Highway Administration, Office of Highway Policy Information 2010). Thus, the potential for NRP to be among several factors contributing to the epidemic of obesity merits further investigation.

AHA Scientific Statement

Particulate Matter Air Pollution and Cardiovascular Disease

An Update to the Scientific Statement From the American Heart Association

Robert D. Brook, MD, Chair; Sanjay Rajagopalan, MD; C. Arden Pope III, PhD; Jeffrey R. Brook, PhD; Aruni Bhatnagar, PhD, FAHA; Ana V. Diez-Roux, MD, PhD, MPH; Fernando Holguin, MD; Yuling Hong, MD, PhD, FAHA; Russell V. Luepker, MD, MS, FAHA; Murray A. Kaufman, MD, MPH; on behalf of the American Heart Association Council on Epidemiology and Prevention, Council on the Kidney in Cardiovascular Disease, and Council on Nutrition, Physical Activity and Metabolism

Abstract—In 2004, the first American Heart Association scientific statement on "Air Pollution and Cardiovascular Disease" concluded that exposure to particulate matter (PM) air pollution contributes to cardiovascular morbidity and mortality. In the interim, numerous studies have expanded our understanding of this association and further elucidated the physiological and molecular mechanisms involved. The main objective of this updated American Heart Association scientific statement is to provide a comprehensive review of the new evidence linking PM exposure with cardiovascular disease, with a specific focus on highlighting the clinical implications for researchers and healthcare providers. The writing group also sought to provide expert consensus opinions on many aspects of the current state of science and updated suggestions for areas of future research. On the basis of the findings of this review, several new conclusions were reached, including the following: Exposure to PM <2.5 μm in diameter ($PM_{2.5}$) over a few hours to weeks can trigger cardiovascular disease–related mortality and nonfatal events; longer-term exposure (eg, a few years) increases the risk for cardiovascular mortality to an even greater extent than exposures over a few days and reduces life expectancy within more highly exposed segments of the population by several months to a few years; reductions in PM levels are associated with decreases in cardiovascular mortality within a time frame as short as a few years; and many credible pathological mechanisms have been elucidated that lend biological plausibility to these findings. It is the opinion of the writing group that the overall evidence is consistent with a causal relationship between $PM_{2.5}$ exposure and cardiovascular morbidity and mortality. This body of evidence has grown and been strengthened substantially since the first American Heart Association scientific statement was published. Finally, $PM_{2.5}$ exposure is deemed a modifiable factor that contributes to cardiovascular morbidity and mortality. **(*Circulation*. 2010;121:2331-2378.)**

tality. There was also an explicit aim to educate clinicians about the importance of this issue, because the cardiovascular health consequences of air pollution generally equal or exceed those due to pulmonary diseases.[1–4] Finally, a list of key remaining scientific questions and strategic avenues for investigation were provided to help foster and guide future research.

The first AHA writing group concluded that short-term exposure to particulate matter (PM) air pollution contributes to acute cardiovascular morbidity and mortality[1] and that exposure to elevated PM levels over the long term can reduce life expectancy by a few years. Although some mechanistic details remained incompletely described, the existing science was deemed adequate to substantiate several plausible biological pathways whereby PM could instigate acute cardiovascular events and promote chronic disease.

There is mounting evidence from a rapid growth of published data since the previous statement related to the harmful cardiovascular effects of air pollution.[3,4] Most, but not all, epidemiological studies corroborate the elevated risk for cardiovascular events associated with exposure to fine PM <2.5 μm in aerodynamic diameter ($PM_{2.5}$). $PM_{2.5}$ generally has been associated with increased risks of myocardial infarction (MI), stroke, arrhythmia, and heart failure exacerbation within hours to days of exposure in susceptible individuals. Several new studies have also demonstrated that residing in locations with higher long-term average PM levels elevates the risk for cardiovascular morbidity and mortality. Some recent evidence also implicates other size fractions, such as ultrafine particles (UFPs) <0.1 μm, gaseous copollutants (eg, ozone and nitrogen oxides [NO_x]), and specific sources of pollution (eg, traffic). In addition, there have been many insights into the mechanisms whereby PM could prove capable of promoting CVDs.[2–4] Air pollutants have been linked with endothelial dysfunction and vasoconstriction, increased blood pressure (BP), prothrombotic and coagulant changes, systemic inflammatory and oxidative stress responses, autonomic imbalance and arrhythmias, and the progression of atherosclerosis. In the interim, the US Environmental Protection Agency (EPA) completed its updated "Air Quality Criteria for Particulate Matter"[5] and afterward strengthened the National Ambient Air Quality Standards (NAAQS) for daily $PM_{2.5}$ levels starting in 2006 (down from 65 to 35 $\mu g/m^3$).[6] The most recent scientific review coordinated by the EPA, the final report of the Integrated Science Assessment for Particulate Matter (http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=216546), has also been made available publicly. These numerous changes and advances provide the rationale for the present updated AHA scientific statement on PM air pollution and CVD. This updated statement is similar in scope, content, and overall structure to the first document; however, it provides many additional conclusions and recommendations that can now be made because of the expanded number and quality of studies.

Objectives and Methods

The primary objective of this scientific statement is to provide a comprehensive updated evaluation of the evidence linking PM exposure with CVDs. The focus of this review is explicitly on PM because the majority of air pollution studies have centered on its cardiovascular effects, and the strength of the evidence makes it possible to provide consensus opinions and recommendations. Except for in a few circumstances, such as when copollutants have been shown to (or not to) modify the responses to PM exposure or to have independent cardiovascular effects in epidemiological studies of major importance, a detailed discussion of other air pollutants (eg, ozone and NO_2) is beyond the scope of this document. Additional objectives are to provide expert consensus opinions on aspects related to the current state of science, to specifically highlight the health and clinical implications of the reviewed findings, and to provide prudent and practical recommendations for measures to reduce PM exposure that might thereby lower the associated cardiovascular risk. This updated scientific statement is structured to first provide a clinical perspective on the cardiovascular risks posed by PM exposure and then briefly review the components of air pollution. The following sections highlight the major findings from epidemiological studies, including mortality, morbidity, and surrogate outcome results. Next, the animal and human mechanistic studies are reviewed, and an overall framework whereby PM exposure could cause CVDs is outlined. Finally, updated consensus opinions and conclusions are provided, followed by suggestions for areas of future research and policy considerations.

Members of the current writing group were selected from across a broad range of disciplines, including cardiovascular and environmental epidemiology and statistics, atmospheric sciences, cardiovascular and pulmonary medicine, basic science research, and public policy. The writing group identified studies published in the English language between January 1, 2004, and March 31, 2009, by a World Wide Web–based literature search using Medline, PubMed, and Google search engines. Key terms included *air pollution* or *particulate matter* plus any of the following: *cardiovascular, myocardial, heart, cardiac, stroke, heart failure, arrhythmia, heart rate variability, autonomic, sympathetic, atherosclerosis, vascular, blood pressure, hypertension, diabetes, metabolic, thrombosis,* and *coagulation*. Additional studies were identified within the references of these publications and by the personal knowledge of the writing group members. A few studies published after March 31, 2009, were added during the review process. All of the identified epidemiological studies that provided mortality data or hard cardiovascular outcomes (eg, MIs) and controlled human exposure protocols were included. In a few circumstances, studies before 2004 were included briefly in the discussion or tables when it was believed that they provided contextual background and/or relevant findings from earlier analyses of ongoing studies (eg, Harvard Six Cities and American Cancer Society [ACS] cohorts) from which new results after 2004 have been published. It is a limitation of the present review that it was not possible to cite all surrogate outcome human studies because of the enormous number of publications. Some were not included, without intentional bias with regard to results, when multiple referenced studies demonstrated similar findings. In such a situation (eg, heart rate variability [HRV]), this

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

limitation was noted within the specific section. A main theme of the present statement is to provide clinical context and recommendations for healthcare providers, and thus, it was beyond the scope and not the intent of this document to include all animal, ex vivo, or toxicological studies. A number of these publications were also not included, without intentional bias with regard to results. The writing group included publications that were believed to have relevant implications for human cardiovascular health, those that formed the foundation of the mechanistic hypotheses, and studies that were deemed of major importance. Finally, the "evidence summary" statements and all points in the conclusions and recommendations represent consensus expert opinions agreed on by all members of the writing group during formal discussions. It is explicitly stated when no such agreement was reached. These statements and the points within Tables 6 and 7 do not represent the result of applying the standard AHA criteria (ie, level and class) to the sum findings of the present review, because those do not apply, but rather the qualitative consensus opinions agreed on by the writing group. The purpose is to provide expert opinions on the comparative relative ranking and the strength of the overall evidence regarding different areas within this field of science.

Perspective on the Air Pollution–Cardiovascular Risk Association

Traditional cardiovascular risk factors account for the major portion of the risk for ischemic cardiac events within a population.[7] Individuals with optimal levels of all risk factors have been shown to have a low lifetime cardiovascular event rate.[8] Thus, control of the traditional risk factors is recognized to be of paramount importance to prevent CVDs. In this context, there has been some debate about the overall clinical relevance and utility of adding novel risk factors to risk-prediction models to incrementally improve their overall predictive value, even when assessed by multiple methodologies.[9] On the other hand, the ability to predict future events by existing models remains imperfect. In addition to several mathematical and statistical explanations for this shortcoming,[10,11] it is important to recognize that the development of vascular or atherosclerotic disease (the factor predicted by most statistical models) is usually a necessary but insufficient cause of future ischemic events in and of itself. Cardiovascular events must also be triggered by an additional factor at some unknowable future time, and therefore, they transpire as a stochastic process within a population.[12] This is one of several reasons why PM air pollution is a uniquely important public health issue among the list of novel risk factors; PM inhalation is an established trigger of cardiovascular events that occur within hours to days after exposure.[12] Because of the ubiquitous and involuntary nature of PM exposure, it may continuously enhance acute cardiovascular risk among millions of susceptible people worldwide in an often inconspicuous manner. Moreover, beyond serving as a simple trigger, PM elicits numerous adverse biological responses (eg, systemic inflammation) that, in premise, may further augment future cardiovascular risk over the long term after months to years of exposure.

Effects of Short-Term Exposure

Time-series studies estimate that a 10-$\mu g/m^3$ increase in mean 24-hour $PM_{2.5}$ concentration increases the relative risk (RR) for daily cardiovascular mortality by approximately 0.4% to 1.0%.[3] Despite theoretical statistical risks ascribed to all individuals, this elevated risk from exposure is not equally distributed within a population. At present-day levels, $PM_{2.5}$ likely poses an acute threat principally to susceptible people, even if seemingly healthy, such as the elderly and those with (unrecognized) existing coronary artery or structural heart disease.[13] Therefore, the absolute risk rather than the RR of exposure may more effectively convey the tangible health burden within a population. A 10-$\mu g/m^3$ increase during the preceding day contributes on average to the premature death of approximately 1 susceptible person per day in a region of 5 million people (based on annual US death rates in 2005).[3,14] Although the dangers to 1 individual at any single time point may be small, the public health burden derived from this ubiquitous risk is enormous. Short-term increases in $PM_{2.5}$ levels lead to the early mortality of tens of thousands of individuals per year in the United States alone.[1,3,5]

Effects of Long-Term Exposure

Cohort studies estimate that the RR associated with living in areas with higher PM levels over the long term is of greater magnitude than that observed from short-term exposure increases (RR between 1.06 and 1.76 per 10 $\mu g/m^3$ $PM_{2.5}$).[3] In this context, the World Health Organization estimated that $PM_{2.5}$ contributes to approximately 800 000 premature deaths per year, ranking it as the 13th leading cause of worldwide mortality.[15] Hence, PM air pollution appears to be an important modifiable factor that affects the public health on a global scale.

Air Pollution

The first AHA statement on air pollution reviewed the size fractions, sources, and chemical constituents of PM and the main gaseous air pollutants: Nitrogen oxides (NO_x; ie, $NO+NO_2$), carbon monoxide (CO), sulfur dioxide (SO_2), and ozone (O_3).[1] Therefore, this section within the updated statement focuses on several other contemporary aspects of air pollution characterization and exposure assessment, particularly in relation to their potential influences on cardiovascular health. In brief, PM is broadly categorized by aerodynamic diameter: All particles <10 μm (thoracic particles [PM_{10}]), all particles <2.5 μm (fine particles [$PM_{2.5}$]), all particles <0.1 μm (UFP), and particles between 2.5 and 10 μm (coarse particles [$PM_{10-2.5}$]). Hence, PM_{10} contains within it the coarse and $PM_{2.5}$ fractions, and $PM_{2.5}$ includes UFP particles. The concentrations of PM_{10} and $PM_{2.5}$ are typically measured in their mass per volume of air ($\mu g/m^3$), whereas UFPs are often measured by their number per cubic centimeter (Table 1). The major source of $PM_{2.5}$ throughout

*Generally not in concentrated plumes or locations of direct source emission impact.

†Typical hourly average concentrations reached in US cities.

‡The 8-hour standard is met when the 3-year average of the 4th highest daily maximum 8-hour average is less than or equal to the indicated number. In January 2010, the EPA proposed a more stringent 8-hour standard within the range of 60 to 70 ppb (http://www.epa.gov/air/ozonepollution/actions.html).

§To attain this standard, the 3-year average of the 98th percentile of the daily maximum 1-hour average at each monitor within an area must not exceed this value.

‖The level is not to be exceeded more than once per year.

¶Typical 24-hour average concentrations.

#The level is not to be exceeded more than once per year on average over 3 years.

**The daily standard is met when the 3-year average of the 98th percentile of 24-hour PM level is less than or equal to the indicated number.

††Although the typical concentrations shown in the table are for $PM_{2.5}$, the lead standard continues to be based on measurements in total suspended particulate.

the world today is the human combustion of fossil fuels from a variety of activities (eg, industry, traffic, and power generation). Biomass burning, heating, cooking, indoor activities, and nonhuman sources (eg, fires) may also be relevant sources, particularly in certain regions.

Common air pollutants and those designated as EPA criteria pollutants (ie, specifically targeted in regulations through limits on emissions or government standards such as the NAAQS) are listed in Table 1. The World Health Organization also provides ambient guidelines (http://www.euro.who.int/Document/E90038.pdf). As a result, many pollutant concentrations are tracked in the United States by nationwide monitoring networks, with up to approximately 1200 sites for O_3 and $PM_{2.5}$. Data are archived by the EPA and are available to the public (http://www.epa.gov/ttn/airs/airsaqs/). O_3 levels exceed the national standard in many areas, and thus, daily information is provided to assist the public in reducing their exposure. A lower standard for ozone concentrations was proposed recently, which will lead to more frequent occurrences of outdoor exposures deemed to be excessive (Table 1). The reporting of $PM_{2.5}$ is also becoming common because of its impact on public health and frequent violations of standards. Current and forecast air quality indices and information on both $PM_{2.5}$ and ozone are available (http://airnow.gov/). At the end of 2008, 211 US counties (or portions of counties) were in nonattainment of the 2006 daily $PM_{2.5}$ NAAQS (http://www.epa.gov/pmdesignations/2006standards/state.htm). On a positive note, the various regulations that have been established have led to substantial reductions in PM and other pollutant levels over the past 40 years in the United States and contributed toward similar improvements in other countries. However, reducing the levels of some pollutants, such as O_3, remains a challenge because of the complex chemical processes that lead to their formation in the atmosphere.[16] The population of many developing nations (China, India, Middle Eastern countries) continues to be exposed to high levels, particularly of PM, which can routinely exceed 100 $\mu g/m^3$ for prolonged periods (http://siteresources.worldbank.org/DATASTATISTICS/Resources/table 3_13.pdf).

Air Pollution Mixtures, Chemistry, and Sources

Detailed information regarding PM sizes, composition, chemistry, sources, and atmospheric interactions is beyond the scope of this document but can be found in the 2004 US EPA Air Quality Criteria for Particulate Matter final report (http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=87903). The source for much of the information provided in this brief summary is this document, unless otherwise specifically referenced. The typical range of ambient concentrations for several air pollutants in the United States, including the latest US NAAQS for the criteria pollutants, is given in Table 1. Classification of air quality according to 1 single pollutant and by size or mass provides an incomplete picture, because ambient air pollution is a complex mixture of gases, particles, and liquids that are continually changing and interacting with each other and natural atmospheric gases. Although $PM_{2.5}$ mass has rightfully attracted considerable attention as a target for regulation and epidemiological study, more than 98% of

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

the air pollutant mass in the mixture we breathe in urban settings is from gases or vapor-phase compounds such as CO, nonmethane hydrocarbons or volatile organic carbons (VOCs), NO_2, NO, O_3, and SO_2. Each of these can have independent and potentially synergistic or antagonistic effects with each other and with PM; however, at present, the cardiovascular health impact of exposure to combinations of air pollutants is not well understood.

Most of the studies linking CVDs with PM exposures have focused on particle mass; thus, this association is evaluated and reported in the majority of epidemiological and toxicological studies reviewed. Although PM is regulated by mass concentration, the aspect of PM most harmful to cardiovascular health may not be best quantified by mass measurement alone. The sum effect of many features related to chemical composition and size/morphology (eg, oxidative stress potential, solubility, charge, surface area, particle count, lung deposition, and stability within the atmosphere and biological tissues) is important to consider. With regard to specific "toxic" compounds within PM, several lines of existing evidence support the idea that transition metals, organic compounds, semiquinones, and endotoxin are likely relevant in relation to promoting CVDs. In addition, certain characteristics of UFPs (eg, high surface area, particle number, metal and organic carbon content) suggest that they may pose a particularly high cardiovascular risk after short-term exposure.[17] Both the additional characterization of "criteria" pollutants and the measurement of several other pollutants (discussed below) are important to inform air quality management practices that involve air quality modeling, as well as epidemiological studies and risk assessment, which ultimately aim to improve risk-reduction strategies.

In addition to their mass concentration, pollutants can be characterized on the basis of their origin or chemical and physical properties. In terms of origin, nitrogen oxides ($NO+NO_2$), CO, SO_2, and $PM_{2.5,}$ as well as carbon dioxide (CO_2), are mainly associated with combustion of fuel or other high-temperature industrial processes. Combustion PM is composed of many chemical compounds, including organic carbon species, elemental or black carbon, and trace metals (eg, lead and arsenic). They range in size from molecular clusters a few nanometers in diameter to light-scattering particles that peak on a mass contribution basis in the diameter range of 200 to 1000 nm (0.2 to 1 μm). UFP numbers are also strongly linked to fresh combustion and traffic-related pollution. Ammonia, methane, pesticides (persistent organic pollutants), reduced sulfur compounds, resuspended dust, and natural coarse particles ($PM_{10-2.5}$) are associated with noncombustion surface or fugitive releases that arise from a variety of human (eg, agriculture) and natural (eg, erosion) activities. Agricultural emissions and releases from a range of industrial processes and waste management are also important sources. Road and wind-blown dust from agricultural practices and from certain industrial facilities (eg, mineral industry) also contribute to these particles, which are typically in the coarse ($PM_{10-2.5}$) or even larger ($>PM_{10}$) range.

In addition to pollutants formed directly by combustion, many others are produced primarily through chemical reactions in the atmosphere among directly emitted pollutants. These are known as secondary pollutants. Sunlight, water vapor, and clouds are often involved in this atmospheric chemistry, which leads to greater oxidation of the pollutants. Examples include PM-associated sulfate, nitrate, and ammonium and many of the organic compounds within $PM_{2.5}$. Besides O_3, which is the most prevalent secondary gaseous oxidant, a number of inorganic and organic acids and VOCs form in the atmosphere. Examples are the hydroxyl radical, peroxyacetyl nitrate, nitric acid, formic and acetic acid, formaldehyde, and acrolein.

VOCs and semivolatile organic compounds (SVOCs), the latter of which are found in both the gas and particle phase, are an additional large class of pollutants. They are associated with both combustion and fugitive emissions, as well as with secondary formation. Key examples are benzene, toluene, xylene, 1,3-butadiene, and polycyclic aromatic hydrocarbons. VOCs are among the 188 hazardous air pollutants listed by the EPA, and their main emission sources have been identified and are regulated (http://www.epa.gov/ttn/atw/mactfnlalph.html). VOCs can undergo reactions that convert toxic substances to less toxic products or vice versa. Many VOCs contribute to the formation of O_3 and are oxidized in the atmosphere, becoming SVOCs, and subsequently partition within particles and contribute to the composition of $PM_{2.5}$, as well as to its mass. A great deal of research has focused on $PM_{2.5}$ in the past decade, which has led to advances in measurement technologies[18] and greater understanding of its chemistry and atmospheric behavior.[19] Nonetheless, understanding is incomplete, particularly with regard to formation of the secondary organic fraction, the relative role of anthropogenic and biogenic emissions to organics, surface chemistry, oxidative potential,[20] and gas-to-particle partitioning.

An alternative to attempting to identify one by one which pollutant(s) or chemical compounds are most harmful is to focus on identifying the sources, which typically emit mixtures of pollutants, of greatest concern. It may be the mixture of pollutants (along with the source from which it is derived, which determines its characteristics) that is most pertinent to human health outcomes. Such information may actually be more relevant for aiding the development of effective air quality policies. One important example reviewed in the epidemiology section is that the evidence continues to grow regarding the harmful cardiovascular effects of traffic-related pollution. Traffic is ubiquitous in modern society, with a sizeable proportion of the population, particularly persons disadvantaged by low socioeconomic status, living close enough (within 500 m) to a major road or a freeway to be chronically exposed to elevated concentrations. Additionally, daily behavior brings most people close to this source, with the average US citizen over 15 years of age spending 55 minutes each day traveling in motor vehicles.[21] However, despite the consistent epidemiological findings, these studies have yet to elucidate which of the many pollutants or other associated risks (ie, noise) produced by traffic are responsible for the increase in risk for CVD. Until the most harmful agents are identified, the only practical manner to potentially reduce health consequences would be to reduce overall traffic and related emissions and to configure cities and lifestyles

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

such that there is greater separation between the people and the source, so that we could spend less time in traffic (a major source of personal exposures in our society). There are also a myriad of other important pollutant sources of known toxic pollutants that have been implicated in health-effect studies (eg, power generation, industrial sources, steel mills, and wood smoke). A better understanding of the factors that influence population exposure to these sources, of how their emissions and mixtures of different sources affect health, and about the factors that make individuals more susceptible will aid in the development of more effective environmental health policies.

Determinants of Air Pollution Exposure

Many aspects of air pollution play a role in the characteristics of population- and individual-level exposures. Pollutants vary on multiple time scales, with emission rates, weather patterns, and diurnal/seasonal cycles in solar radiation and temperature having the greatest impact on concentrations. The temporal behavior of a pollutant is also governed by its formation rate and the length of time it remains in the atmosphere. As such, the concentrations of many air pollutants tend to co-vary. For example, NO_x and CO are emitted during combustion, as are some particle constituents (eg, elemental carbon) and VOCs, and thus, their concentrations peak during rush hour. On the other hand, O_3 and other photochemical oxidants, including secondary $PM_{2.5}$ and secondary VOCs, peak in the afternoon, particularly given certain meteorologic conditions (eg, more sunshine). Among the common air pollutants, O_3 and $PM_{2.5}$ have the longest atmospheric lifetime and thus can build up over multiple days and spread, by the prevailing winds, over large geographic regions. This can lead to similarities in their temporal and spatial patterns over broad regions and to greater numbers of people being exposed to similar levels, thus lessening interindividual variability in exposure.

Periods of suppressed horizontal and vertical mixing in the lower atmosphere lead to the buildup of multiple pollutants. These situations are most common under slow-moving or stationary high-pressure systems, which bring light winds, a stable atmosphere, and more sunshine. The frequency and seasonality of these meteorologic conditions and how they affect concentrations vary geographically, which leads to differences in the characteristics of pollution episodes from the western to the eastern United States, as well as within these regions.

The commonality of meteorology and emission sources leads to covariation in pollutant concentrations on multiple temporal and spatial scales, which makes it more challenging for epidemiological studies to identify the health effects of individual pollutants and the effects of copollutants or mixtures. Studies that depend on daily counts of mortality or morbidity events have difficulties separating the effects of the different pollutants in the urban mix. Even prospective panel studies measuring specific end points on a subdaily time scale are hindered by pollutant covariation. Some of these challenges could potentially be addressed by undertaking studies covering multiple geographic locations with differences in the structure of pollutant covariation due to different meteorology and source mixes. Indeed, this has been done, at least in part, by several existing multicity studies. Consistency in the findings in individual studies conducted in different cities also helps isolate the pollutants that may be more responsible for the health effects. The consistent positive findings with certain pollutants (eg, PM mass concentration) have helped strengthen the evidence regarding PM_{10} and $PM_{2.5}$ effects, but regardless of location, there remains the strong underlying commonality of fossil fuel combustion for many pollutants.

A final issue to consider is the cardiovascular health effects of exposures that occur at the personal level because of the different microenvironments or activities an individual experiences (eg, time in traffic, indoor sources, secondhand tobacco smoke, occupational exposure, and degree of indoor penetration of ambient PM into homes) versus the effects of exposures from less variable urban- to regional-scale ambient concentrations (ie, background pollution that most individuals encounter more uniformly). Personal monitoring demonstrates substantial variations among individual pollution exposures or characteristics among those living within the same metropolitan area and even the same neighborhood.[22,23] However, the differing additive, synergistic, and/or confounding effects on cardiovascular health of these 2 contrasting components of a person's overall exposure have not been well described. For the most part, the magnitude of the findings reported by the major epidemiological studies (see next section) are indicative of the effects of the urban- to regional-scale ambient concentrations. Actual exposures to all pollutants also vary at the personal level. The cardiovascular health importance of these individual-level variations (above and beyond the effect of urban/regional levels) remains largely unknown, in part because it has been difficult to quantify. The degree to which measurement of personal exposures or more precise exposure assessment (eg, use of geographic information systems, land-use regression models, spatial-temporal models, and adjustments for indoor penetration) can reduce the effects of exposure misclassification in epidemiological studies also remains to be fully elucidated.[24–26]

Epidemiological Studies of Air Pollution

Epidemiological studies of air pollution have examined the health effects of exposures observed in real-world settings at ambient levels. Associations between relevant health end points and measures of air pollution are evaluated while attempting to control for effects of other pertinent factors (eg, patient and environmental characteristics). Despite substantial study and statistical improvements and the relative consistency of results, some potential for residual confounding of variables and publication bias[27] of positive studies are limitations to acknowledge. Probably the most relevant, well-defined, and extensively studied health end points include mortality (all-cause and cause-specific), hospitalizations, and clinical cardiovascular events. This section reviews the results of the epidemiological research with a focus on new studies since the first AHA statement was published,[1] as well as on the cardiovascular health implications. In sum, numerous studies of varied design have been published in the interim that significantly add to the overall weight of evi-

dence that exposure to air pollutants at present-day levels contributes to cardiovascular morbidity and mortality.

Mortality and Air Pollution

Time-Series and Related Studies

Time-series and case-crossover studies explore associations between short-term changes in air pollution and daily changes in death counts. The sum of current evidence supports the findings of an earlier review[28] that demonstrated that short-term elevations in daily PM levels lead to a greater absolute risk for CVD-related mortality than for all other causes. Even if similar acute RR elevations (≈1.01) are estimated between cardiovascular and pulmonary mortality, CVDs account for 69% of the increase in absolute mortality rates compared with 28% for pulmonary diseases attributable to short-term PM exposure. Recently, more rigorous modeling techniques have been used in attempts to better estimate pollution-mortality associations while controlling for other time-dependent confounding covariables.[29,30] There have been well over 100 published daily time-series studies reporting small but statistically significant PM-mortality associations that have been the subject of quantitative reviews or meta-analyses.[3,27,31–33] Table 2 summarizes recent multicity analyses and studies published since 2004.

To address concerns about city selection bias, publication bias, and influences of copollutants, several large, multicity, daily time-series studies have been conducted worldwide. One of the largest was the National Morbidity, Mortality, and Air Pollution Study (NMMAPS). Published reports from this study included as few as 20 US cities,[44,45] as many as 100 cities,[46,47] and more recently, data for hundreds of counties (Table 2).[48] The observed relationship between PM exposure and excess mortality remained independent of several gaseous copollutants (NO_2, CO, or SO_2). Recent analyses suggest that O_3 may also independently contribute to cardiopulmonary mortality risk[49,50]; however, coexposures to secondary particle pollutants may be responsible in part for this latter association.[51]

Several studies have also been conducted outside the United States, including the Air Pollution and Health: A European Approach (APHEA and APHEA-2) projects, which examined daily PM-related mortality effects in multiple cities.[36,52] PM air pollution was significantly associated with daily mortality counts for all-cause, cardiovascular, and respiratory mortality (Table 2). Further analyses of the European data suggest that CVD deaths are also associated with exposure to NO_2[53] and CO.[54] A few new time-series studies have also confirmed similar increases in cardiovascular mortality related to short-term PM exposure in China[55–57] and Bangkok, Thailand.[42] Additional multicity studies have been conducted worldwide with analyses of CVD deaths (Table 2).[38–42,58–60] Finally, in a recent analysis that included several Asian

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

cities, SO_2, NO_2, O_3, and PM_{10} were all associated with excess cardiovascular mortality.[42]

In an attempt to evaluate the coherence of multicity studies across continents, the Air Pollution and Health: A Combined European and North American Approach (APHENA) study analyzed data from the APHEA, NMMAPS, and Canadian studies.[61] The combined effect on all-cause mortality ranged from 0.2% to 0.6% for a 10-$\mu g/m^3$ elevation in daily ambient PM_{10}, with the largest effects observed in Canada. Among individuals older than 75 years, the effects were greater for cardiovascular mortality than for overall and pulmonary mortality (0.47% to 1.30%). Older age (>75 years) and higher rates of unemployment were related to greater PM mortality risks in both continents. Higher NO_2 levels were associated with larger PM_{10} effects on mortality, particularly in Europe. Finally, there appeared to be no lower-limit threshold below which PM_{10} was not associated with excess mortality across all regions.

Evidence Summary

The overall evidence from time-series analyses conducted worldwide since publication of the first AHA statement[1] confirms the existence of a small, yet consistent association between increased mortality and short-term elevations in PM_{10} and $PM_{2.5}$ approximately equal to a 0.4% to 1.0% increase in daily mortality (and cardiovascular death specifically) due to a 10-$\mu g/m^3$ elevation in $PM_{2.5}$ during the preceding 1 to 5 days (Table 2).

Cohort and Related Studies

Although short-term changes in PM concentrations have deleterious health effects, longer-term exposures may have a more pertinent clinical health effect on cardiovascular morbidity and mortality given that individuals are typically exposed to higher air pollution levels over extended periods of time. An additional source of exposure variability that has been exploited in epidemiological studies is spatial variability, which includes differences in average ambient concentrations over extended periods of time across metropolitan areas or across smaller communities within local areas. Recent emphasis has been on prospective cohort studies that control for individual differences in multiple confounding variables and cardiovascular risk factors. A summary of these studies is presented in Table 3 and Figure 1. These cohort studies generally demonstrate larger overall mortality effects than the results of time-series analyses.

Harvard Six Cities and ACS Studies

Two landmark cohort-based mortality studies, the Harvard Six Cities[62] and the ACS studies,[66] were reported in the mid 1990s and were discussed previously.[1] In both, $PM_{2.5}$ and sulfate particulate pollution were associated with increases in all-cause and cardiopulmonary disease (Table 3). In addition, intensive independent reanalyses[63] corroborated the original findings of both studies and resulted in innovative methodological contributions that demonstrated the robustness of the results to alternative modeling approaches. In both the Harvard Six Cities[62,64] and the ACS[67] studies, PM air pollution–related mortality was substantially higher for cardiovascular- than for pulmonary-related causes.

Since 2004, there have been further analyses of both studies. Laden et al[64] extended the mortality follow-up of the Harvard Six Cities cohort for an additional 8 years. $PM_{2.5}$ associations, similar to those found in the original analysis, were observed for all-cause and CVD mortality (Table 3). Furthermore, reductions in $PM_{2.5}$ concentrations for the extended follow-up period were associated with reduced mortality risk. Further analysis suggested that the health effects of changes in exposure were seen primarily within 2 years.[84] In addition to confirming the earlier mortality relationship, the recent observations suggest that the adverse health effects mediated by longer-term PM air pollution exposure can be estimated reasonably accurately by the previous few years of particle levels.

Extended analyses of the ACS cohort that emphasize efforts to control for the effects of other covariates and risk factors have corroborated the previously reported mortality associations with particulate and sulfur oxide pollution.[68] Elevated mortality risks were most strongly associated with $PM_{2.5}$. Coarse particles ($PM_{10-2.5}$) and gaseous pollutants, except for SO_2, were generally not significantly related to mortality. In another extended analysis,[67] the death certificate classifications of underlying causes of death due to $PM_{2.5}$ exposures were observed to be principally ischemic heart disease, arrhythmias, heart failure, and cardiac arrest. Finally, recent additional analyses attempted to control for the fact that variations in exposure to air pollution across cities or within cities may correlate with socioeconomic or demographic gradients that influence health and susceptibility to environmental exposures.[85,86] When controlled for individual risk factor data, the mortality associations for intrametropolitan $PM_{2.5}$ concentration differences within the Los Angeles, Calif, area were generally larger than those observed in the full cohort across metropolitan areas.[69] However, the results were somewhat sensitive to the inclusion of zip code–level ecological variables, which suggests potential contextual neighborhood confounding. Krewski et al[70] subsequently observed that full adjustments for multiple ecological covariates did not reduce the estimated $PM_{2.5}$-related mortality effect. The association for ischemic heart disease mortality in particular was highly robust across various study areas and modeling strategies and after controlling for both individual and ecological covariates.

An additional recent analysis of the ACS cohort evaluated the health effects of ozone compared with $PM_{2.5}$.[87] The findings reconfirmed the independent cardiovascular mortality increase related to fine-particle exposure. However, after adjustment for $PM_{2.5}$, ozone was associated solely with an elevated risk of death due to respiratory causes; there was no independent risk of ozone exposure on CVD-related mortality. This suggests that the positive findings reported in NMMAPS[50] regarding cardiopulmonary mortality and short-term ozone exposure could be explained at least in part by the enhanced risk of mortality due to lung disease categories.

Additional Cohort Studies

Several additional cohort studies have been published in the past few years (Table 3). Eftim and colleagues[65] studied 2 very large "cohorts" of US Medicare participants who lived in locations included in the Harvard Six Cities and ACS studies. Effects of $PM_{2.5}$ exposure on mortality for the period 2000 to 2002 were estimated after controlling for multiple factors, although not at the individual patient level. For all-cause mortality, the $PM_{2.5}$-mortality associations were larger than those observed in the Harvard Six Cities or ACS cohorts. In an additional analysis of 13.2 million US Medicare participants for the time period 2000 to 2005,[71] $PM_{2.5}$-mortality associations were shown to be similar to those observed in the Harvard Six Cities and ACS studies in the East and Central regions of the United States (and when the data were pooled for the entire United States). However, $PM_{2.5}$ was not associated with mortality in the Western United States or for the oldest age group (>85 years old). These findings generally corroborate the earlier cohort studies and add evidence that aspects of exposure (PM sources or composition) and patient susceptibility might play important roles in determining the health risks.

In a cohort of postmenopausal women without prior CVD from the Women's Health Initiative Observational Study,[72] an association between longer-term $PM_{2.5}$ exposure (median follow-up of 6 years) and cardiovascular events (primary end point) was observed. After adjustment for age and other risk factors, an incremental difference of 10 $\mu g/m^3$ $PM_{2.5}$ was associated with a 24% (95% confidence interval [CI]9% to 41%) increase in all first cardiovascular events (fatal and nonfatal, with a total of 1816 cases). Notably, an incremental difference of 10 $\mu g/m^3$ $PM_{2.5}$ was also associated with a large 76% (95% CI 25% to 147%) increase in fatal cardiovascular events, based on 261 deaths. The risks for both coronary heart disease and strokes were found to be similarly elevated. Interestingly, within-city $PM_{2.5}$ gradients appeared to have larger cardiovascular effects than those between cities, although this difference was not statistically significant. Finally, overweight women (body mass index >24.8 kg/m^2) were at relatively greater cardiovascular risk due to particulate air pollution than leaner women. Noteworthy aspects of this study were improved assessment of the end points by medical record review (rather than by death certificate) and long-term particle exposure estimation. The control for individual-level confounding variables was also superior to that of previous cohort studies.

In another cohort of women, a subset of the Nurses' Health Study from the northeastern United States,[73] an increase of 10 $\mu g/m^3$ modeled estimates of PM_{10} exposures was associated with an approximately 7% to 16% increased risk of all-cause mortality and a 30% to 40% increase in fatal coronary heart disease, depending on the level of adjustment for covariates. This study found that the strongest health risks for all-cause and cardiovascular mortality were seen in association with the average PM_{10} exposure during the previous 24 months before death. Similar to the findings of the Women's Health Initiative, the cardiovascular mortality risk estimates were larger than those of previous cohort studies. In addition, obese women (body mass index >30 kg/m^2) were at greater relative risk, and the increases in mortality (all-cause and cardiovascular) were larger than the effects on nonfatal events. The results were also in accordance with the latest Harvard Six Cities analyses[64] that show that exposure over the most recent preceding 1 to 2 years can accurately estimate the majority of the health risks due to longer-term PM air pollution exposures.

The pollution-mortality association has also been assessed in several other cohort studies in the United States and Europe (Table 3).[76–83] In a recent analysis of the Adventist Health Study of Smog (AHSMOG) cohort with a much

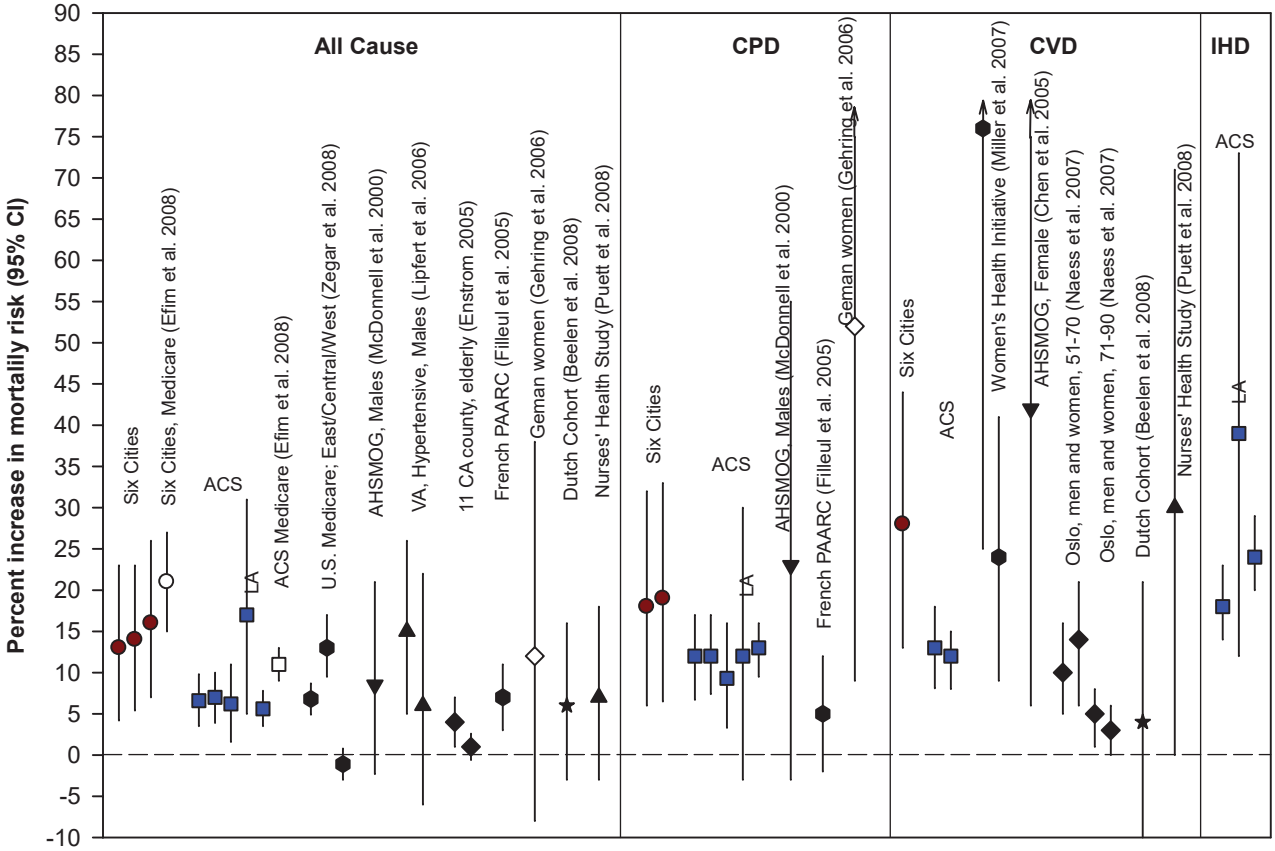

Figure 1. Risk estimates provided by several cohort studies per increment of 10 $\mu g/m^3$ in $PM_{2.5}$ or PM_{10}. CPD indicates cardiopulmonary disease; IHD, ischemic heart disease.

longer follow-up than the original studies,[74,88] fatal coronary heart disease was significantly associated with $PM_{2.5}$ among females but not males.[75] These observations along with the remarkably robust health effects in the Women's Health Initiative Observational Study and Nurses' Health Study suggest that women may be at special risk from PM exposure. The overall cohort study evidence demonstrates that a 10-$\mu g/m^3$ increase in $PM_{2.5}$ exposure is in general positively associated with excess mortality, largely driven by increases in cardiopulmonary or cardiovascular deaths (Figure 1). Independent results from the Women's Health Initiative Study,[72] the US Medicare cohorts,[71] the German women cohort,[80] and the intracity Oslo (Norway) study[81] contribute substantially to this evidence. Although the Dutch cohort,[82] AHSMOG,[74,75] French PAARC (Pollution Atmosphérique et Affections Respiratoires Chroniques [air pollution and chronic respiratory diseases]),[79] Veterans Affairs hypertensive male study,[77] and 11 CA county[78] studies observed increased mortality risks associated with higher $PM_{2.5}$ exposure that were statistically significant in some analyses, the observed health risks were less robust. A finding that is somewhat consistent across the Veterans Affairs hypertensive male study,[77] 11 CA county,[78] Oslo,[81] and US Medicare cohorts[71] is that the $PM_{2.5}$-mortality effect estimates tend to decline with longer periods of follow up or in a substantially older cohort. These studies also often observed elevated mortality risks according to alternative indicators of air pollution exposure, especially metrics of traffic-related exposure.

Evidence Summary

The overall evidence from the cohort studies demonstrates on average an approximate 10% increase in all-cause mortality per 10-$\mu g/m^3$ elevation in long-term average $PM_{2.5}$ exposure. The mortality risk specifically related to CVD appears to be elevated to a similar (or perhaps even greater) extent, ranging from 3% to 76% (Table 3). This broader estimated range in risk compared with the short-term effects observed in time series is due to several recent cohort studies[72,73] that demonstrated larger cardiovascular mortality risks (eg, >30%) than in earlier cohort observations. This may reflect superior aspects of these studies that allowed for a better characterization of the cardiovascular risk of long-term exposure, the fact that these cohorts consisted of only women, or other unclear reasons. Compared with cardiovascular mortality, there is less existing evidence to support an increase in the risk for nonfatal cardiovascular events related to $PM_{2.5}$ exposure among the existing cohort studies, because many of them did not specifically investigate nonfatal outcomes, and several of the more recent studies reported nonsignificant relationships.[72,73]

Natural Experiment and Intervention Studies

Several studies have shown improvements in health outcomes in association with exposures using well-defined natural experiments or interventions, such as abrupt reductions in air pollution[89–91] or changes over a longer period of time.[64,92]

Small but statistically significant drops in mortality were associated with an 8½-month copper smelter strike that resulted in sharp reductions in sulfate PM and related air pollutants across 4 Southwest states, even after controlling for other factors.[93] Data from US Medicare enrollment files were used to estimate the association between changes in monthly mortality rates for US counties and average $PM_{2.5}$ concentrations for the previous 12 months.[94] $PM_{2.5}$-mortality associations were observed at the national scale but not the local scale, which raises concerns about possible statistical confounding due to unmeasured individual and ecological variables as a cause for any positive findings in this study. However, a recent large study found that reductions in PM air pollution exposure on a local scale (across US counties) over a 2-decade period (1980s and 1990s) were associated with increased life expectancy even after controlling for changes in socioeconomic, demographic, and proxy smoking variables.[95] Indeed, a decrease of 10 $\mu g/m^3$ in the long-term $PM_{2.5}$ concentration was related to an increase in mean life expectancy of 0.61 ± 0.20 years.

Hospitalization Rates

There are many daily time-series or case-crossover studies that have evaluated associations between cardiovascular hospitalizations and short-term changes in air pollution. Because of the great number of publications, all studies (particularly those focusing on nonparticulate air pollutants) cannot be discussed individually. Nevertheless, Table 4 presents a comparison of pooled estimates of percent increase in RR of hospital admission for general cardiac conditions across a previous meta-analysis of 51 published estimates (COMEAP [Committee on the Medical Effects of Air Pollutants]) and results from many selected multicity studies published after 2004. Several studies before 2004 are included in Table 4 only to demonstrate the consistency of effect.

Because of its comparatively large size and importance, the results of a recent analysis of Medicare files in 204 US urban counties with 11.5 million individuals older than 65 years merit discussion. Daily changes in $PM_{2.5}$ levels were associated with a variety of cardiovascular hospital admission subtypes.[103] A 10-$\mu g/m^3$ increase in $PM_{2.5}$ exposure was related to increases in hospitalizations for cerebrovascular disease by 0.81% (95% CI 0.3% to 1.32%), peripheral vascular disease by 0.86% (95% CI −0.06% to 1.79%), ischemic heart disease by 0.44% (95% CI 0.02% to 0.86%), arrhythmias by 0.57% (95% CI −0.01% to 1.15%), and heart failure by 1.28 (95% CI 0.78% to 1.78%). The most rapid effects, which occurred largely on the same day of $PM_{2.5}$ elevation, were seen for cerebrovascular, arrhythmia, and heart failure admissions. Ischemic heart disease events tended to increase to a greater extent 2 days after exposures. A consistent finding was that the cardiovascular effects of pollution were much stronger in the Northeast than in other regions. In fact, there were few significant associations in Western US regions. It was speculated that these differences reflected variations in particle composition (eg, greater sulfate in the East and nitrate components in the West) and pollution sources (eg, power generation in the East and transportation sources in the West). In a follow-up analysis by Peng et al,[104] $PM_{10-2.5}$ levels were not statistically associated with cardiovascular hospitalizations after adjustment for $PM_{2.5}$. This suggests that the smaller particles (ie, $PM_{2.5}$) are principally responsible for the cardiovascular hospitalizations attributed in prior studies to the combination of both fine and coarse particles (ie, PM_{10}). Given the differences between the size fractions, the results imply that particles and their components derived from combustion sources (ie, $PM_{2.5}$) are more harmful to the cardiovascular system than larger coarse particles. Finally, there is some evidence that gaseous pollutants may also instigate hospitalizations. Hospital admissions for cardiovascular causes, particularly ischemic heart disease, were found to rise in relation to the previous-day and same-day level of SO_2, even after adjustment for PM_{10} levels.[105]

Table 5. Comparisons of Estimated Percent Increase in Risk of Ischemic Heart Disease Events due to Concurrent or Recent Daily PM Exposure

Event/Study Area	Primary Source	Exposure Increment	% Increase (95% CI)
MI events–Boston, Mass	Peters et al[110] 2001	10 $\mu g/m^3$ $PM_{2.5}$	20 (5.4–37)
MI, 1st hospitalization–Rome, Italy	D'Ippoliti et al[112] 2003	30 $\mu g/m^3$ TSP	7.1 (1.2–13.1)
MI, emergency hospitalizations–21 US cities	Zanobetti and Schwartz[113] 2005	20 $\mu g/m^3$ PM_{10}	1.3 (0.2–2.4)
Hospital readmissions for MI, angina, dysrhythmia, or heart failure of MI survivors–5 European cities	Von Klot et al[114] 2005	20 $\mu g/m^3$ PM_{10}	4.2 (0.8–8.0)
MI events–Seattle, Wash	Sullivan et al[115] 2005	10 $\mu g/m^3$ $PM_{2.5}$	4.0 (−4.0–14.5)
MI and unstable angina events–Wasatch Front, Utah	Pope et al[13] 2006	10 $\mu g/m^3$ $PM_{2.5}$	4.8 (1.0–6.6)
Tokyo metropolitan area	Murakami et al[109] 2006	TSP >300 $\mu g/m^3$ for 1 h vs reference periods <99 $\mu g/m^3$	40 (0–97)*
Nonfatal MI, Augsburg, Germany	Peters et al[111] 2004	Exposure to traffic 1 h before MI (note: not PM but self-reported traffic exposure)	292 (222–383)
Nonfatal MI, Augsburg, Germany	Peters et al[116] 2005	Ambient UFP, $PM_{2.5}$, and PM_{10} levels	No association with UFP or $PM_{2.5}$ on same day. Positive associations with $PM_{2.5}$ levels on 2 days prior

Evidence Summary

Excess cardiovascular mortality and increased rates of hospitalizations are similarly associated with day-to-day changes in PM air pollution (Tables 2 and 4). However, significant differences between geographic regions in the risk relationships have been observed, and more investigation is required to explain this heterogeneity.

Specific Cardiovascular Events/Conditions

Ischemic Heart Disease

Among the cohort studies that provided relevant results, the ACS study found a relationship between increased risk for ischemic heart disease death and long-term exposure to elevated $PM_{2.5}$ levels (Table 3).[67,69,106] Indeed, ischemic cardiac events accounted for the largest relative (RR 1.18, 95% CI 1.14 to 1.23) and absolute risk for mortality per 10-$\mu g/m^3$ elevation in $PM_{2.5}$.[67] A survival analysis of US Medicare data for 196 000 survivors of acute MI in 21 cities showed the risk of an adverse post-MI outcome (death, subsequent MI, or first admission for congestive heart failure) was increased with higher exposure to PM_{10}.[107] Data from the Worcester Heart Attack study also found that long-term exposure to traffic-related air pollution was associated with significantly increased risk of acute MI.[108] However, in the Women's Health Initiative[72] and the Nurses' Health Study,[73] only disease categories that included fatal coronary events, but not nonfatal MI alone, were statistically elevated in relation to $PM_{2.5}$. The effect size for cardiovascular mortality was much larger and much more statistically robust than for nonfatal events such as MI in both studies.

Various time-series and case-crossover studies have also reported increased ischemic heart disease hospital admissions associated with short-term elevated concentrations of inhalable and/or fine PM air pollution.[31,40,103] In the US Medicare study, a reduction of $PM_{2.5}$ by 10 $\mu g/m^3$ was estimated to reduce ischemic heart disease admissions in 204 counties by 1523 (95% posterior interval 69 to 2976) cases per year.[103] Several studies have also found positive associations between elevated PM or traffic exposures over a period as brief as a few hours[109–111] or a few days and an elevated risk for MI (Table 5).[13,110,112–115] In general, acute increases in risk for ischemic heart disease events have been observed consistently, even as rapidly as 1 to 2 hours after exposure to elevated PM, in case-crossover analyses.[109–111] Other studies have reported an increased risk for MI shortly after exposure to traffic. Peters et al[111] reported in 691 subjects in Augsburg, Germany, a strong association (odds ratio 2.92, 95% CI 2.22 to 3.83) between onset of MI and traffic exposure within the past hour, although whether this was a result of the air pollution or a combination of other factors (eg, noise and stress) is not certain. Additional analyses did not report an association between recent UFP exposures and MI onset; however, the levels of $PM_{2.5}$ and several gaseous pollutants 2 days earlier were related to MI risk.[116] The lack of relationship between MI and UFPs may be due to the fact that the levels were measured regionally and remote from the localized source and may therefore reflect exposure misclassification. Finally, in the only study in which participating subjects had coronary angiograms performed previously, ischemic cardiac events were found to occur in relation to PM air pollution exposure solely among individuals with obstructive coronary atherosclerosis in at least 1 vessel.[13] This finding suggests the importance of patient susceptibility (eg, the presence of preexisting coronary artery disease) for PM to trigger an acute ischemic event within hours to days after exposure.

Heart Failure

In the ACS cohort study, it appeared that deaths due to arrhythmias, heart failure, and cardiac arrest (RR 1.13, 95% CI 1.05 to 1.21 per 10 $\mu g/m^3$) were also associated with

prolonged exposure to $PM_{2.5}$, although not as strongly as ischemic heart disease mortality,[67] although potential mortality misclassification on death certificates makes the actual cause of death not entirely certain in all circumstances. Heart failure rates or mortality associations were not reported in the other cohort studies.

Daily hospitalizations for heart failure have also been associated with short-term changes in PM exposure.[31] Heart failure associations with PM were observed in a large daily time-series analysis of $PM_{2.5}$ and cardiovascular and respiratory hospitalizations by use of a national database constructed from US Medicare files.[103] A 10-$\mu g/m^3$ increase in concurrent-day $PM_{2.5}$ was associated with a 1.28% (95% CI 0.78% to 1.78%) increase in heart failure admissions, the single largest cause for hospitalization in this cohort. A reduction of $PM_{2.5}$ by 10 $\mu g/m^3$ was estimated to reduce heart failure admissions in 204 counties by 3156 (95% posterior interval 1923 to 4389) cases per year.[103] Another analysis in Medicare recipients in 7 US cities found a 10-$\mu g/m^3$ increase in concurrent-day PM_{10} was associated with a 0.72% (95% CI 0.35% to 1.10%) increase in heart failure admissions.[117] Traffic-related air pollution has also been shown to be significantly associated with increased mortality risk after acute heart failure.[118] Finally, a study from Utah's Wasatch Front area explored longer lagged-exposure periods and found that a 14-day lagged cumulative moving average of 10 $\mu g/m^3$ $PM_{2.5}$ was associated with a 13.1% (95% CI 1.3% to 26.2%) increase in heart failure admissions.[119]

Cerebrovascular Disease

Among the cohort studies that provided pertinent results, the Women's Health Initiative reported significant increases in both nonfatal stroke (hazard ratio 1.28, 95% CI 1.02 to 1.61) and fatal cerebrovascular disease (hazard ratio 1.83, 95% CI 1.11 to 3.00) per 10-$\mu g/m^3$ elevation in prolonged exposure to $PM_{2.5}$.[72] However, no significant association between stroke mortality and PM air pollution was found in the ACS study.[67]

Several studies have also reported small but statistically significant associations between short-term PM exposure and cerebrovascular disease. Daily time-series studies of stroke mortality in Seoul, Korea,[120,121] observed that elevated air pollution (including measures of PM, NO_2, CO, and O_3) was associated with increases in stroke mortality. When analyzed separately by stroke type,[121] the pollution association was associated with ischemic but not hemorrhagic stroke. Risk of stroke mortality was also associated with daily increases in PM_{10} and NO_2 in Shanghai, China.[56] A daily time-series study in Helsinki, Finland,[122] found that $PM_{2.5}$ and CO were associated with stroke mortality in the warm but not the cold seasons. Several studies have also observed increased stroke or cerebrovascular hospital admissions associated with increased exposure to PM or related pollutants.[31,38,40,46,123–125] For example, a study of hospital admissions for Medicare recipients in 9 US cities[125] found that several measures of air pollution (PM_{10}, CO, NO_2, and SO_2) 0 to 2 days before admission were associated with ischemic but not hemorrhagic stroke. Studies of ischemic stroke and transient ischemic attacks based on population-based surveillance have also been conducted in Dijon, France,[126] where O_3 exposure (but not PM_{10}) was associated with ischemic stroke, and in Corpus Christi, Tex,[127] where both $PM_{2.5}$ and O_3 were associated with ischemic strokes and transient ischemic attacks.

Peripheral Arterial and Venous Diseases

There have been only a few studies that have explored a relationship between air pollution and peripheral vascular diseases. Studies using Medicare data for 204 US counties observed nearly statistically significant positive associations between daily changes in measures of PM pollution and hospitalizations for peripheral vascular diseases.[103,104] The ACS cohort found no association between other atherosclerotic and aortic aneurysm deaths and long-term $PM_{2.5}$ exposure.[67]

Recently, a case-control study from the Lombardy region of Italy found a 70% increase in risk of deep vein thrombosis per 10-$\mu g/m^3$ elevation in long-term PM_{10} level.[128] This is the first observation that particulate air pollution can enhance coagulation and thrombosis risk in a manner that adversely affects the venous circulation in addition to the arterial cardiovascular system.

Cardiac Arrhythmias and Arrest

Several studies have observed associations between fine PM and related pollutants and cardiac arrhythmias, often based on data from implanted cardioverter-defibrillators.[129–136] However, no clear pollution-related associations were observed in studies from a relatively clean metropolitan area, Vancouver, British Columbia, Canada,[137,138] or from a relatively large study in Atlanta, Ga.[139] Similarly, pollution-related associations have been observed with cardiac arrest in Rome, Italy,[140] and Indianapolis, Ind,[141] but not in Seattle, Wash.[142,143] The mixed results may reflect different PM compositions due to different sources or variations among the methods used.

Evidence Summary

On the basis of the available epidemiological studies that have reported the associations between PM exposures with specific subsets of cardiovascular outcomes (morbidity, mortality, or hospitalizations), the existing level of overall evidence is strong for an effect of PM on ischemic heart disease, moderate (yet growing) for heart failure and ischemic stroke, and modest or mixed for peripheral vascular and cardiac arrhythmia/arrest (Table 6).

Ambient Air Pollution and Subclinical Pathophysiological Responses in Human Populations

It is likely that many subclinical physiological changes occur in individuals in response to $PM_{2.5}$ exposures that do not become overtly manifest as a cardiovascular event (eg, death or MI). The illustration of these more subtle responses bolsters the plausibility of the observable outcome associations and provides insight into the pathways whereby air

pollutants mediate CVDs. The "Biological Mechanisms" section discusses the hypothesized global pathways and reviews the studies related to the fundamental cellular/molecular mechanisms elucidated by controlled human and animal exposures and toxicological/basic science experiments. The following section reviews the recent evidence that ambient exposure to air pollution can mediate potentially harmful subclinical cardiovascular effects. In general, many positive associations are found (Table 6). Numerous complex interactions between variations in the characteristics, sources, and chemistry of the particles, coupled with diversity in time frames, mixtures of exposures, and degrees of individual susceptibility, likely explain some of the disparity among findings.

Systemic Inflammation

There is evidence that under some circumstances, exposure to ambient PM can be associated with elevated circulating proinflammatory biomarkers that are indicative of a systemic response after PM air pollution inhalation that is not limited to the confines of the lung. Early reports found associations with day-to-day variation in acute-phase proteins, such as C-reactive protein (CRP), fibrinogen, or white blood cell counts,[144–147] as reviewed previously.[1] Limited evidence on the association between cumulative PM exposures and fibrinogen levels and counts of platelets and white blood cells was also available.[148]

A number of more recent studies have reported positive associations with short-term ambient PM exposure and day-to-day elevations in inflammatory markers. These include increases in CRP in an elderly population[149] and individuals with coronary atherosclerosis[150]; CRP and fibrinogen in young adults[151] and elderly overweight individuals[152]; and CRP, tumor necrosis factor-α (TNF-α), and interleukin (IL)-1β in children.[153] Recent evidence has also been found for an upregulation of circulating soluble adhesion molecules (eg, intercellular adhesion molecule-1) in 92 Boston, Mass–area individuals with diabetes[154] and 57 male subjects with coronary artery disease in Germany.[150] In a larger analysis of 1003 MI survivors, also in Germany, CRP was not related to PM exposure; however, ambient particle number concentration and PM_{10} were associated with increased IL-6 and fibrinogen, respectively.[155] Short-term levels of in-vehicle $PM_{2.5}$ have also been linked to increases in CRP among healthy highway patrol troopers.[156] In a follow-up analysis, elevations in certain particulate components of traffic pollution (eg, chromium) were associated with increased white blood cell counts and increased IL-6 levels.[157] Short-term changes in ambient PM levels have also been linked to acute (1 to 3 days later) alterations in biomarkers of inflammation, oxidative stress, and platelet activation among elderly adults with coronary artery disease living in retirement communities in Los Angeles, Calif.[158,159] Pollutants associated with primary combustion (eg, elemental and black carbon, primary organic carbon) and UFPs rather than $PM_{2.5}$ appeared to be strongly associated with adverse responses in this population.

Regarding more long-term exposures,[160] a positive association between white blood cell count and estimated long-term 1-year exposure to PM_{10} was reported in the Third National Health and Nutrition Examination Survey. Among 4814 adults in Germany, small increases in annual mean $PM_{2.5}$ (3.9 $\mu g/m^3$) were associated with increases in high-sensitivity CRP by 23.9% and in fibrinogen by 3.9% among men only. Estimated long-term traffic exposure was not related to inflammatory changes in either sex.[161]

Several studies, including some with improved exposure assessment,[162] some that included analyses of large population cohorts,[163,164] and a recent evaluation of long-term annual PM_{10} levels in England,[165] have not found a relationship between particulate exposure and inflammation. It is

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

conceivable that differences in the magnitude or character of the inflammatory response will occur because of variations in the particulate chemistry and duration/intensity of exposures. Certain individuals may also be more susceptible. The evidence suggests that subjects with underlying cardiovascular risk factors and the metabolic syndrome may exhibit stronger associations.[152,160,166] Conversely, antiinflammatory medications such as statins may mitigate the actions of ambient particles.[152,155] All together, there is some evidence for a positive association between recent and long-term PM exposure and a systemic proinflammatory response; nevertheless, there is variation in the strength and consistency of changes among the variety of biomarkers and patient populations evaluated (Table 6).

Systemic Oxidative Stress

A state of oxidative stress refers to a condition in which levels of free radicals or reactive oxygen/nitrogen species (eg, O_2^-, H_2O_2, $ONOO^-$) are higher than normal (eg, healthy individuals in whom they are countered by homeostatic processes such as antioxidants) and thus are capable of exerting many adverse biological effects (eg, lipid/protein/deoxyribonucleic acid [DNA] oxidation, initiation of proinflammatory cascades). Although many biomarkers of differing systemic responses are available (eg, lipid or protein oxidation products), oxidative stress may occur at the local cellular/tissue level and not be directly observable by circulating markers. In addition, oxidative stress is often induced by and elicits inflammatory processes. The 2 processes are biologically linked. Therefore, human studies investigating the effect of PM on oxidative stress per se are difficult to perform. Only a few studies have directly investigated the occurrence of systemic oxidative stress in humans in relation to ambient PM exposure. Three studies of young adults conducted in Denmark demonstrated elevations in biomarkers of protein, lipid, or DNA oxidation in relation to PM exposure from traffic sources.[167–169] In a study of 76 young adults from Taipei, Taiwan,[151] the investigators found evidence of increased levels of 8-hydroxy-2′-deoxyguanosine adducts in DNA in relation to short-term elevations in ambient PM. Two studies have also demonstrated increases in plasma homocysteine, evidence that exposure to ambient PM can elevate this circulating mediator of oxidative stress.[170,171] Finally, Romieu et al[172] found that dietary supplementation with omega-3 polyunsaturated fatty acids might be capable of altering the systemic oxidative stress response (reduction in copper/zinc superoxide dismutase and glutathione) induced by air pollutants among residents living in a nursing home in Mexico City, Mexico. Because of the relatively small number of studies, more investigation is required to make firm conclusions and to understand the nature of the systemic oxidative stress response potentially induced by ambient PM (Table 6).

Thrombosis and Coagulation

Early reports indicated that increased plasma viscosity[144] and elevated concentrations of fibrinogen[146] are associated with short-term changes in ambient PM concentrations. More recent evidence was found for an upregulation of circulating von Willebrand factor in 57 male subjects with coronary artery disease in Germany[150] and 92 Boston-area individuals with diabetes.[154] Riediker[157] found that components of in-vehicle $PM_{2.5}$ were also related to increased von Willebrand factor and decreased protein C among highway patrol troopers. In the Atherosclerosis Risk in Communities study, a 12.8-$\mu g/m^3$ elevation in ambient PM_{10} was associated with a 3.9% higher von Willebrand factor level,[173] but only among those with diabetes. There was no linkage between PM_{10} exposure and fibrinogen or white blood cell levels.

Alterations in other markers that indicate changes in thrombosis, fibrinolysis, and global coagulation have also been reported. An immediate elevation in soluble CD40-ligand concentration, possibly reflecting platelet activation, recently was found to be related to ambient UFP and accumulation-mode particle ($PM_{0.1–1.0}$) levels in patients with coronary artery disease.[155] Ambient PM_{10} levels have also been associated with augmented platelet aggregation 24 to 96 hours after exposure among healthy adults.[174] In this study, there were no concomitant observable changes in thrombin generation, CRP, or fibrinogen induced by PM_{10}. Increases in plasminogen activator inhibitor-1 and fibrinogen levels have been noted in healthy subjects,[151] as well as elevated plasminogen activator inhibitor-1 in patients with coronary artery disease only,[175] in association with ambient PM levels in Taipei. Chronic indoor pollution exposure to biomass cooking in rural India has also been associated with elevated circulating markers of platelet activation.[176] Recently, Baccarelli et al[128,177] demonstrated in healthy subjects and among individuals with deep venous thrombosis living in the Lombardy region of Italy that prothrombin time was shortened in relation to recent and long-term ambient PM_{10} concentrations. Nevertheless, some studies found no effects of ambient pollution,[178] nor have significant changes been reported among all the biomarkers or subgroups of individuals investigated.[150,154,170,173] Similar to the study on systemic inflammation, the results related to thrombosis/coagulation are quite variable given the differences in study designs, patients, biomarkers evaluated, and pollutants; however, these adverse effects appear somewhat more consistent among higher-risk individuals (Table 6).

Systemic and Pulmonary Arterial BP

Several studies have reported that higher daily PM levels are related to acute increases in systemic arterial BP (approximately a 1- to 4-mm Hg increase per 10-$\mu g/m^3$ elevation in PM).[179–184] In a small study of patients with severe heart failure,[185] pulmonary artery and right ventricular diastolic BP were found to increase slightly in relation to same-day levels of PM. Chronic exposure to elevated $PM_{2.5}$ was associated with increased levels of circulating endothelin (ET)-1 and elevated mean pulmonary arterial pressure in children living in Mexico City.[186] These results may explain in part the risk for heart failure exacerbations due to PM

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

exposure; however, not all studies of systemic arterial BP have been positive.[187–189]

Recently, Dvonch et al[190] demonstrated significant associations between increases in systolic BP and daily elevations in $PM_{2.5}$ across 347 adults living in 3 distinct communities within metropolitan Detroit, Mich. Much larger effects were observed 2 to 5 days after higher $PM_{2.5}$ levels within a specific urban location of southwest Detroit (8.6 mm Hg systolic BP increase per 10-$\mu g/m^3$ $PM_{2.5}$) than throughout the entire region or cohort (3.2 mm Hg). This suggests that specific air pollution sources and components contribute significantly to the potential for PM exposure to raise BP. Interestingly, it was recently reported in a crossover study of 15 healthy individuals that systolic BP was significantly lower (114 versus 121 mm Hg) during a 2-hour walk in Beijing, China, while the subjects were wearing a high-efficiency particulate-filter facemask than when they were not protected.[191] Wearing the facemask was also associated with increased HRV, which suggests that the rapid BP-raising effects of particle inhalation may be mediated through the autonomic nervous system (ANS). In a similar fashion,[192] reducing exposure to particulate pollution from cooking stoves was shown to be associated with lower systolic (3.7 mm Hg, 95% CI −8.1 to 0.6 mm Hg) and diastolic (3.0 mm Hg, 95% CI −5.7 to −0.4 mm Hg) BP among Guatemalan women than among control subjects after an average of 293 days. These findings demonstrate that indoor sources of PM (eg, cooking, biomass) may have important cardiovascular health consequences and that reductions in particulate exposure are capable of lowering BP, and they suggest that chronic exposure to PM air pollution may alter long-term basal BP levels. Even given the rapid variability of BP on a short-term basis and the numerous factors involved in determining individual responses (eg, patient susceptibility, PM composition, and time frames of exposure), overall, it appears that ambient PM can adversely affect systemic hemodynamics, at least under certain circumstances (Table 6).

Vascular Function

In the first ambient PM study related to changes in vascular function, O'Neill et al[193] reported that both endothelium-dependent and -independent vasodilation were blunted in relation to air pollution levels in Boston. The largest changes occurred in association with sulfate and black carbon, suggestive of coal-burning and traffic sources, respectively. Significant adverse responses were observed within 1 day yet were still present and slightly more robust up to 6 days after exposure. Moreover, the adverse responses occurred solely among diabetic individuals and not in patients at risk for diabetes mellitus. Two other studies[184,194] also demonstrated impaired vascular function due to short-term changes in ambient PM among diabetic patients. In the study by Schneider et al,[194] endothelium-dependent vasodilation was blunted during the first day, whereas small-artery compliance was impaired 1 to 3 days after elevated ambient PM levels. Interestingly, higher concentrations of blood myeloperoxidase were related to a greater degree of endothelial dysfunction, which suggests that white blood cell sources of reactive oxygen species (ROS) may be involved.

In healthy adults, very short-term exposure to elevated levels of ambient PM from traffic sources while exercising for 30 minutes near roadways[195] and when resting by bus stops for 2 hours[196] has been related to impaired endothelium-dependent vasodilation. Daily changes in ambient gaseous pollutants (SO_2 and NO_x) in Paris, France, have also been associated with impaired endothelium-dependent vasodilation among nonsmoking men.[197] Finally, indoor particulate air pollution may also be harmful to vascular function. Bräuner and colleagues[198] recently reported that reductions in 48-hour $PM_{2.5}$ levels due to filtering of air in subjects' homes resulted in improved microvascular vascular function among elderly subjects. Nevertheless, changes in short-term ambient PM levels have not been linked with impaired conduit[197] or microvascular[178] endothelial function in all studies. Even when the few negative studies are considered, the overall evidence supports the concept that ambient PM is capable of impairing vascular function, particularly among higher-risk individuals (eg, those with diabetes) and after traffic-related exposure (Table 6).

Atherosclerosis

A few cross-sectional studies have reported an association between measures of atherosclerosis in humans and long-term exposures to ambient air pollution levels. The first study to demonstrate this relationship was an analysis of data from 798 participants in 2 clinical trials conducted in the Los Angeles area. A cross-sectional contrast in exposure of 10 $\mu g/m^3$ $PM_{2.5}$ was associated with an adjusted nonsignificant 4.2% (95% CI −0.2% to 8.9%) increase in common carotid intima-media thickness[199]; however, in certain subgroups of patients, such as women, the effect was much larger (13.8%, 95% CI 4.0% to 24.5%). In a population-based sample of 4494 subjects from Germany,[200] it was found that residential proximity to major roadways was associated with increased coronary artery calcification. A reduction in distance from a major road by half was associated with a 7% (95% CI 0.1% to 14.4%) higher coronary artery calcium score. Proximity to traffic was also related to an increased risk for peripheral artery disease in women but not men.[201] In an analysis of 3 measures of subclinical disease (carotid intima-media thickness, coronary calcium, and ankle-brachial index) among 5172 adults from the Multi-Ethnic Study of Atherosclerosis, only common carotid intima-media thickness was modestly (yet significantly) associated with 20-year exposure to $PM_{2.5}$.[202] In a related study from the same cohort, abdominal aortic calcium was associated with long-term $PM_{2.5}$ exposure, especially for residentially stable participants who resided near a $PM_{2.5}$ monitor.[203] Although it appears that long-term exposure to higher levels of ambient PM might accelerate the progression of atherosclerosis, more investigations are needed (Table 6).

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

Heart Rate Variability

Numerous studies have continued to explore associations between daily changes in PM air pollution exposure and alterations (typically reductions) in HRV metrics, putative markers of cardiac autonomic balance.[129,149,156,204–242] Recent observations in the Normative Aging Study cohort have shown strong effect modification of the PM-HRV relationship by obesity and genes that modulate endogenous oxidative stress or xenobiotic metabolism, such as glutathione S-transferase M1, methylenetetrahydrofolate reductase, and the hemochromatosis gene.[207,243,244] Additional findings suggest protective effects of statins, dietary antioxidants, and B vitamins, as well as omega-3 polyunsaturated fatty acids.[205,207,215,243,244] These results suggest that pathways that reduce endogenous oxidative stress have a protective effect that mitigates reductions in HRV due to ambient PM exposure.

However, the overall results are not entirely consistent. Some studies have reported increases in HRV mediated by PM, specifically among younger healthy people and patients with chronic obstructive lung disease.[156,208,216] Nevertheless, the general pattern suggests that PM exposure is associated with increased heart rate and reductions in most indices of HRV among older or susceptible individuals, such as those with obesity and the metabolic syndrome. Typically, time-domain measures (eg, standard deviation of normal RR intervals) and total power are reduced within hours after exposure. Most, but not all, pertinent studies have also found that the largest reduction in power is within the high-frequency domain. In sum, these observations provide some evidence that ambient PM air pollution exposure rapidly reduces HRV, a surrogate marker for a worse cardiovascular prognosis (Table 6). Although studies corroborating changes in autonomic activity by other methods (eg, microneurography or norepinephrine kinetics) have not been performed, the HRV findings are perhaps reflective of the instigation of a generalized cardiovascular autonomic imbalance due to relatively greater parasympathetic than sympathetic nervous system withdrawal.

Cardiac Ischemia and Repolarization Abnormalities

There has been limited direct evidence for the actual induction of cardiac ischemia or repolarization abnormalities in the electrocardiogram (ECG) by exposure to ambient levels of PM.[223,245] Recent follow-up analyses from the initial ULTRA study (Exposure and Risk Assessment for Fine and Ultrafine Particles in Ambient Air)[245] suggested that traffic-related combustion pollutants were most strongly related to the promotion of ST-segment depression among elderly nonsmokers during exercise stress testing.[246] Moreover, even very acute $PM_{2.5}$ exposure within the past 1 or 4 hours has been associated with cardiac ischemia during exercise.[247] New findings support these associations in elderly subjects[248] and in patients with coronary artery disease in Boston.[249] In the latter study, traffic-related PM was most strongly related to the incidence of ST-segment depression during 24-hour Holter monitoring, and the risk for ischemia was greatest within the first month after a cardiac event among patients with diabetes. Overall, there is a modest level of evidence that PM exposure can promote cardiac ischemia in susceptible individuals (Table 6).

Epigenetic Changes

There have been relatively few studies examining gene–air pollution exposure interactions, and most have done so while investigating a small number of loci for genetic polymorphisms. Although some studies have suggested greater air pollution susceptibility with one or another genomic polymorphism,[207,243,244] few have evaluated the potential for epigenetic changes after exposures. Reduced levels of DNA methylation have been linked to aging, oxidative stress, and CVD. Recently, Baccarelli et al[250] have shown among 718 elderly participants in the Normative Aging Study that short-term exposures (over 1 to 7 days) to $PM_{2.5}$ and black carbon are associated with decreased "global" DNA methylation in long interspersed nucleotide elements. It was posited that oxidative stress from air pollution exposure could have interfered with the capacity for methyltransferases to interact with DNA or altered the expression of genes involved in the methylation process. This observed effect of pollution exposure was analogous to changes seen with 3.4 years of aging in the cohort. Additional findings among workers in a furnace steel plant support these observations.[251] Nevertheless, the mechanisms involved and the cardiovascular implications of these preliminary, although provocative, epigenetic changes require more investigation.

Traditional Cardiovascular Risk Factors

In addition to the fact that individuals with traditional risk factors are likely to be at higher risk for cardiovascular events due to PM exposure, air pollutants may also promote the development of these risk factors over a prolonged period of time. Few published studies have investigated this possibility. A report from the Multi-Ethnic Study of Atherosclerosis has demonstrated that residential proximity to major roadways was associated with a higher left ventricular mass index as measured by cardiac magnetic resonance imaging.[252] The degree of increase was analogous to a 5.6-mm Hg increase in systolic BP among the study participants. This suggests that traffic-related exposures may have increased left ventricular mass by chronically elevating systemic arterial BP, a common cause of left ventricular hypertrophy. However, other mechanisms cannot be excluded, such as systemic inflammation and oxidative stress, which could potentially activate neurohormonal pathways (eg, ANS imbalance, renin-angiotensin system) that could directly mediate such a finding. In addition, a recent study of adults older than 30 years of age (n=132 224) participating in the National Health Interview Survey reported a significant association between self-reported hypertension and estimated annual $PM_{2.5}$ exposure using US EPA monitoring data.[253] A 10-$\mu g/m^3$ elevation in $PM_{2.5}$ was associated with an

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

adjusted odds ratio of 1.05 (CI 1.00 to 1.10) for the presence of hypertension. The increase in risk was found only among non-Hispanic whites. These studies provide some initial evidence that longer-term PM exposures may augment the risk for developing chronically elevated BP levels or even overt hypertension.

Brook et al[254] have also demonstrated a novel relationship between a metric of long-term traffic exposure (NO_2 level by residence) and the odds of having the diagnosis of diabetes mellitus among patients in 2 respiratory clinics in Ontario, Canada. In women only, the odds ratio of diabetes was 1.04 (95% CI 1.00 to 1.08) for each increase of 1 parts per billion (ppb) of NO_2. Across the interquartile range (4 ppb NO_2), exposures were associated with nearly a 17% increase in odds for diabetes mellitus. The first biological support for this finding comes from a study in Iran that demonstrated that the previous 7-day-long exposure to PM_{10} was independently associated with worse metabolic insulin sensitivity among 374 children 10 to 18 years of age.[255] These findings suggest that the systemic proinflammatory and oxidative responses due to long-term PM air pollution exposure could potentially increase the risk for developing clinically important aspects of the metabolic syndrome, such as hypertension and diabetes mellitus. Further studies in this regard are warranted.

Evidence Summary

Table 6 provides a consensus qualitative synopsis based on the expert opinions of the writing group members of the overall level of existing support, linking each surrogate or intermediate cardiovascular outcome with exposures to PM at ambient concentrations, based solely on the database of observational studies.

Additional Epidemiological Findings and Areas of Continued Research

Responsible Sources and Pollution Constituents

Although PM concentration (mass per cubic meter) has been associated with cardiovascular events in numerous studies, the specific particulate constituents and the sources responsible remain less clear. Despite the fact that it is a difficult undertaking, several epidemiological studies have attempted to identify the culprit components within the PM mixtures. With regard to PM-associated inorganic ions (nitrate and sulfate), it has been suggested that the overall toxicological data do not clearly implicate these compounds as responsible for mediating the cardiovascular health effects of $PM_{2.5}$.[256] Nevertheless, sulfate particles have been associated with cardiopulmonary mortality in the ACS and Harvard Six Cities studies.[62,68] A recent time-series analysis among 25 US cities found that cardiovascular risk was increased when PM mass contained a higher proportion of sulfate, as well as some metals (aluminum, arsenic, silicon, and nickel).[257] It is possible that these positive findings represent sulfate serving as a marker for an effect mediated by a toxic PM mixture derived from commonly associated sources (eg, coal combustion). Nevertheless, a direct role for particle sulfate in causing cardiovascular events cannot be excluded entirely.[256]

In California, short-term exposures to several different PM constituents that likely reflect combustion-derived particulates, including organic and elemental carbon and nitrates, were most strongly associated with higher cardiovascular mortality.[258] Certain metals (zinc, titanium, potassium, and iron) and sulfate levels in the winter months were also positively related. Similarly, ambient levels of organic and elemental carbon have been most strongly linked among PM constituents with hospitalizations for CVDs in multipollutant models in a study among 119 US cities.[259] Finally, $PM_{2.5}$ composed of higher levels of elemental carbon, along with the metals nickel and vanadium,[48] has also been linked with greater risks for cardiovascular hospitalizations.[260] These results support that the chemistry or composition of the $PM_{2.5}$ (eg, organic/elemental carbon and certain metals) along with the responsible source from which these mixtures are derived (eg, fresh combustion, traffic) may play important roles in determining the risk for cardiovascular events. However, the extent to which these constituents mediate specific responses, alone or together, and their importance beyond the concentration of $PM_{2.5}$ mass alone represent an area of active research that requires more investigation to reach firm conclusions.

Many experiments have demonstrated the especially toxic properties and strong oxidizing potential of the smallest particle sizes (eg, UFP) and of the specific chemical species typically rich within this size fraction (eg, transition metals, organic compounds, and semiquinones).[261] Although some epidemiological evidence suggests that exposure to ultrafine compounds[17] may be associated with higher cardiovascular risk (eg, an elevation of UFP count by 9748/cm^3 has been associated with an increase in cardiovascular mortality of approximately 3% within 4 days in Erfurt, Germany[262]) and adverse responses,[158,159] there have been few such studies because they are challenging to conduct, for numerous reasons. Moreover, there are few UFP monitors, and the levels measured at regional sites may not accurately reflect an individual person's exposure because of marked spatial heterogeneity, because the concentrations are dominated by local point sources of fresh combustion (eg, roadways). This could help explain some of the previously negative study findings.[116]

Similarly, coarse particulates between 0.25 and 1.0 μm in diameter may affect the cardiovascular system,[221,264,265] and although the available data related to hard events and cardiovascular mortality have suggested a relationship,[265,266] recent findings have been less consistent.[104] In the most recent time-series analysis of 112 US cities, coarse PM was independently associated with elevated all-cause, stroke, and pulmonary, but not cardiovascular, mortality after controlling for $PM_{2.5}$.[43] Coarse PM was also not associated with either fatal or nonfatal cardiovascular events after controlling for $PM_{2.5}$ levels in the Nurses' Health Study[267] or the Women's Health Initiative cohort analyses.[72] Additional research is required to establish whether there are independent health effects of the other

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

particulate size fractions beyond those posed by fine particles. On the other hand, $PM_{2.5}$ mass concentration is the metric most consistently associated with cardiovascular morbidity and mortality. It remains to be determined whether this reflects limitations of available data, the long-lived and regionally homogenous atmospheric nature of $PM_{2.5}$, that few studies have investigated the independent effects of the other sizes, difficulties in performing epidemiology studies with adequate UFP exposure estimates, or that specific constituents within the fine PM fraction (or another unidentified agent correlated with that fraction) are actually responsible for causing cardiovascular events. Although particles <0.1 μm (ie, UFPs) do make up a small fraction of $PM_{2.5}$ mass, the correlation between UFP particle number and total $PM_{2.5}$ mass concentration is often weak. Because of their minute size, UFPs make up only a small portion of the total $PM_{2.5}$ mass, even though they represent the largest actual number of particles within fine PM. They also have the highest surface area and a differing surface chemistry. Therefore, changes in the underlying UFP concentration do not likely account for or explain the linkages between $PM_{2.5}$ mass concentration and cardiovascular events observed in large multicity studies. The overall epidemiological evidence thus indicates that fine PM poses an independent cardiovascular risk and that any putative effects of these other size fractions cannot fully explain the observed $PM_{2.5}$–cardiovascular morbidity/mortality relationship.

On the other hand, there is mounting evidence for a distinctive role played by motor vehicle traffic–related exposures in elevating cardiovascular risk.[108,111,268,269] Lipfert et al[76,77] interpreted the results of their analysis of the Veterans Affairs hypertensive male cohort as suggesting that traffic density was a more "significant and robust predictor of survival in this cohort" than $PM_{2.5}$. Analyses of the Oslo,[81] Dutch,[82] AHSMOG,[74,75,88] French PAARC,[79] and German women cohorts[80] and related studies from areas in the United Kingdom,[270] Canada,[271] Norway,[272] and Rome[273] found that measures that often indicate traffic-related exposure (NO_2, NO_x, traffic density, and living near major roads) were also associated with increased mortality. Long-term 5-year average traffic-generated air pollution exposure has been associated with an increased risk of fatal MI (odds ratio 1.23, 95% CI 1.15 to 1.32 per 31-$\mu g/m^3$ increase in NO_2) but not nonfatal MI in Stockholm County, Sweden.[274] The results mirror the results of several cohort studies[72,73] that found that air pollution exposures appeared to be more strongly linked with cardiovascular mortality than nonfatal events. Recently, an analysis from a cohort in the Netherlands demonstrated that several metrics of traffic-related air pollution exposure remained significantly associated with increased risk for cardiovascular events even after adjustment for higher levels of traffic noise.[275]

The effect of long-term traffic-related exposure on incidence of fatal and nonfatal coronary heart disease was recently assessed after adjustment for background air pollutants and cardiovascular risk factors in 13 309 adults in the Atherosclerosis Risk in Communities study.[276] Interestingly, background chronic ambient $PM_{2.5}$ concentrations were not related to the interpolated traffic exposure levels or to heart disease outcomes, which supports the highly localized nature of traffic sources of exposure. After 13 years of follow-up in 4 US communities, individuals residing within the highest quartile of traffic density had a relative risk of 1.32 (95% CI 1.06 to 1.65) for fatal and nonfatal heart disease events. Despite multiple statistical adjustments, the investigators also acknowledged the possibility for residual confounding as a potential source of bias. The specific traffic-related pollution components, such as UFP or gaseous-phase chemicals (eg, SVOCs), that are responsible for the positive findings among these studies remain unknown. The close proximity to roadways within these epidemiological studies (eg, 400 m) required to observe an association with elevated cardiovascular risk, however, matches the atmospheric fate of these shorter-lived pollutants. The findings may thus suggest the existence of cardiovascular health effects mediated by specific air pollutants rather than $PM_{2.5}$ per se. There is room for improvement in assessment of traffic exposures in epidemiological research, and better approaches are now being incorporated into research projects, such as accounting for associated factors (eg, noise or spatial autocorrelation with socioeconomic status).[275,277]

Geographic differences in cardiovascular risk due to PM have also been observed across US regions, with more consistent or stronger effects observed in Eastern versus Western states.[71,103,257] Differences between North American and European cities have also been reported.[61] PM exposures are typically, but not always,[258] associated with larger effects during warmer months (spring through fall) than in the winter.[45,103,257] Variations in pollution characteristics (eg, sulfate), time spent outdoors, air conditioning usage and particle penetration indoors, ambient temperature and meteorology, and mobile (eg, diesel) or stationary (eg, coal combustion) sources of exposure may help explain these differences. Finally, variations in the cardiovascular risk posed by PM may also occur because of heterogeneity in the metric of exposure, such as personal versus background regional,[25] indoor versus outdoor sources, and differences in intracity versus intercity gradients.[69] A better understanding of the responsible constituents and sources is important and could potentially lead to more targeted and effective regulations. On the other hand, finding continued evidence that the adverse cardiovascular health effects cannot be linked conclusively to a particular or specific chemical species or source of pollution but rather that they occur in response to a variety of exposure types or mixtures would support the present-day policy of reducing exposure to overall fine particulate mass to achieve public health benefits.

Time Course and Concentration-Response Relationships

Many studies have demonstrated that PM air pollution exposure does not simply advance the mortality by a few days of critically ill individuals who would have otherwise died (eg, mortality displacement or "harvesting").[278,279] There also appears to be a monotonic (eg, linear or log-linear) concentration-response relationship between $PM_{2.5}$ and mor-

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

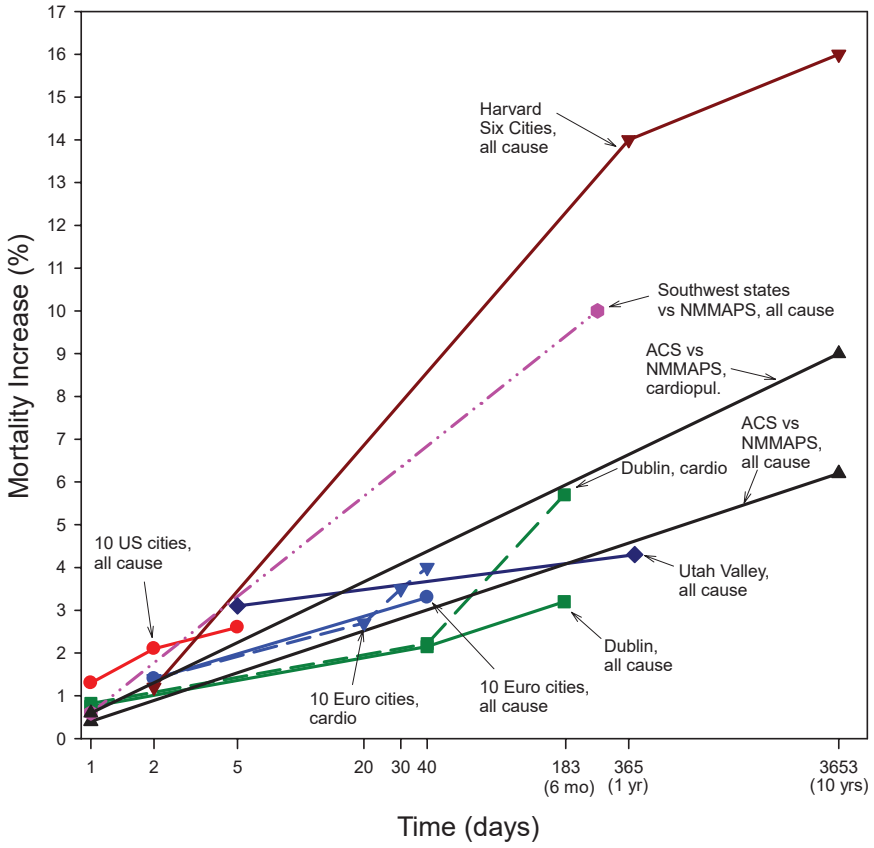

Figure 2. Comparison of estimates of percent change in mortality risk associated with an increment of 10 $\mu g/m^3$ in $PM_{2.5}$ or 20 $\mu g/m^3$ of PM_{10} or British Smoke (BS) for different time scales of exposure (log scale of approximate number of days, updated and adapted from Pope[281a]). Euro indicates European; cardio, cardiovascular disease; and cardiopul, cardiopulmonary.

tality risk observed in cohort studies that extends below present-day regulations of 15 $\mu g/m^3$ for mean annual levels, without a discernable "safe" threshold.[67,70,84] Cardiovascular risk due to particle exposure was also shown to extend below 15 $\mu g/m^3$ in the recent analysis of the Women's Health Initiative Observational Study.[72] This monotonic association supports the idea that any reduction in particulate pollution will translate into health benefits within a population of people, each with their own individual level of susceptibility. It also suggests that a larger decrease in $PM_{2.5}$ exposures will produce a greater reduction in mortality. Finally, a recent analysis of the literature provided important new insights into the nature of the PM exposure-response relationship.[280] The risk for cardiovascular mortality was shown to increase in a linear fashion across a logarithmically increasing dosage of inhaled fine-particle levels that ranged from ambient PM air pollution (≈0.2 mg/d), through secondhand smoke (≈1 mg/d), to active smoking (200 mg/d). This means that the exposure response is extremely steep at very low PM levels (ie, ambient air pollution) and flattens out at higher concentrations (ie, active smoking). This may help explain the seemingly incongruent and comparatively very high degree of cardiovascular risk posed by the much lower levels of PM exposure from ambient pollution and secondhand smoke versus the much higher doses due to active smoking. Thus, the cardiovascular system may be extremely sensitive to very low levels of PM inhalation as encountered with ambient pollution.

At present, the underlying nature and full scope of the temporal-risk relationship posed by longer-term PM exposures remain uncertain.[2,281] The writing group members did concur that the available epidemiological studies demonstrate larger cardiovascular risks posed by more prolonged exposures to higher PM levels than observed over only a few days (Figure 2). Cohort studies using Cox regression survival analyses (over months to years) are capable of evaluating a more complete portion of the temporal-risk relationship than time-series analyses over only a few days that use Poisson regression. However, given the lack of complete information, no conclusions could be drawn on the full magnitude of the augmented risk posed by chronic exposures, the time window (a few months versus decades) required to exhibit this enhanced risk, the underlying biological causes, the extent to which statistical differences between study types explain the variations in risk, and whether clinically relevant chronic CVDs are precipitated by chronic exposures. Some writing group members believe it is important to differentiate as 2 distinct issues the potentially greater effect of long-term exposures on increasing the risk for acute events (eg, cardiovascular mortality) compared with the putative effect on initiating or accelerating the development of chronic CVD processes per se (eg, coronary atherosclerosis). As such, it is possible that the greater risks observed in cohort studies could be capturing the fact that repetitive exposures over months or years augment the risk for sudden cardiovascular events in susceptible people, without actually worsening an underlying "chronic" disease process.

On the one hand, the available studies demonstrate that the majority of the larger risk-effect sizes posed by longer-term versus short-term exposures appear to be manifested within

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

only 1 to 2 years of follow-up. Extending the duration of follow-up increases cardiovascular risk, but to a progressively smaller degree over time (Figure 2). The discrepancy in the effect sizes among study types (eg, cohort versus time-series studies) could also reflect differences in statistical methodologies or population susceptibilities.[282–284] Recent attempts to investigate this matter[64,84] suggest that the risk for acute events associated with chronic exposures may be reasonably well estimated by only the most proximal 1 to 2 years of PM levels. The most recent time frames of exposure also explain a substantial portion of the excess cardiovascular risk observed in several cohort studies.[70,72,73,83] These findings bolster the argument that relatively rapid and pliable (and potentially reversible) biological responses, such as the instigation of plaque instability or the enhanced thrombotic potential caused by PM-mediated inflammation or endothelial dysfunction (which can occur and abate over only a few weeks to months), could explain the biology responsible for this greater relative risk.

On the other hand, cogent alternative arguments can be made to explain the differences in relative risk between the cohort and time-series studies. The likely high correlation of a recent year's exposure levels with exposures over many years, as well as the uniform rank ordering of exposure severity over time among cities, can explain why only a short period of PM exposure assessment is required to understand the risk of longer-term exposures. In addition, no studies have evaluated the potential risks of exposure over decades or a lifetime. PM augments the ability of traditional risk factors to accelerate the development of atherosclerosis in experimental settings. As such, it is also plausible that long-term exposures may enhance cardiovascular risk to an even greater extent by increasing an individual's susceptibility for future cardiovascular events or acute exposures. In addition, the full extent of this possibility may not be illustrated by the limited follow-up period (4 to 5 years) of the majority of cohort studies. The writing group thus agreed that this important issue requires more investigation.

It is also possible that these 2 explanations are not mutually exclusive. Furthermore, it cannot be concluded from available information that a long period of time is required for reductions in PM levels to translate into a decrease in cardiovascular risk. On the contrary, reductions in secondhand smoke[285] and PM air pollution levels[64,84,90,95] appear to produce fairly rapid decreases in cardiovascular event rates, within a few months to years.[284] At present, the available data do not allow for firm conclusions regarding the underlying biology and the full extent of the potentially nonuniform PM exposure–to–cardiovascular risk temporal relationship.

Susceptibility to Air Pollution Exposure

Susceptibility refers to a heightened risk for a particular cardiovascular end point or event to occur compared with the general population at the same concentration of PM exposure. Typically, this is indicative of an underlying medical condition (eg, diabetes) or personal characteristic (eg, old age) that causes this enhanced risk. This is in contrast to the term "vulnerability," which refers to a population of individuals at greater risk for more frequent or high levels of exposures.

Earlier studies reviewed in the first AHA scientific statement[1] suggested that susceptible populations include the elderly; individuals with diabetes; patients with preexisting coronary heart disease, chronic lung disease, or heart failure; and individuals with low education or socioeconomic status. In the ACS study, current and previous smokers appeared to be at the same or greater degree of risk.[67] Among more recent studies, the Women's Health Initiative also reported positive findings among active smokers and an elevated risk for cardiovascular mortality induced by $PM_{2.5}$.[72] Conversely, current smokers were found to be at no increased risk for cardiovascular mortality in response to $PM_{2.5}$ exposure in the Nurses' Health Study.[73] Thus, the effect modification of smoking status requires more investigation. The APHENA study of European and North American cities recently confirmed that elderly and unemployed individuals are at higher risk of short-term PM exposure.[61] In a multicity time-series study in Asia, women, the elderly, and individuals with lower education and socioeconomic status were also shown to be at elevated risk.[286] A few additional studies have reported some evidence of susceptibility to short-term PM exposures among older individuals, people with diabetes, and those with a lower level of education.[287–289] Finally, a recent study illustrated that present-day levels of $PM_{2.5}$ likely increase the risk for a cardiac event within a few days of exposure principally (or even solely) among individuals with preexisting significant coronary artery disease, even if they are seemingly healthy (eg, without anginal symptoms). Patients without obstructive lesions on heart catheterization were not at any risk for $PM_{2.5}$-induced myocardial events over the short term.[13] This is not surprising, because most acute cardiovascular events occur among individuals with underlying vulnerable substrate (eg, unstable plaques) and not in individuals with normal coronary arteries.

Obesity has been newly recognized as a possible susceptibility factor. Two cohort studies have shown that a greater body mass index enhances the susceptibility for PM-induced cardiovascular mortality, at least among women.[72,73] Although individuals with diabetes showed a trend toward greater risk in the Women's Health Initiative,[72] hypertension, high cholesterol, smoking, elderly age, education, and income did not alter the risk association. Overall, there appears to be little effect modification by race, hypercholesterolemia, or BP among the studies. Finally, sex may also be a risk-effect modifier. The particularly robust risk estimates of the 2 cohort studies that included only women,[72,73] the fact that PM increased cardiovascular risk in female but not male participants of the AHSMOG study,[75] and the multicity time-series findings in Asia[286] suggest that women may be at greater risk for cardiovascular mortality related to PM. Further studies are needed to clarify whether obese individuals and women are indeed susceptible populations.

Biological Mechanisms

There has been substantial improvement in our understanding of the biological mechanisms involved in PM-mediated

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

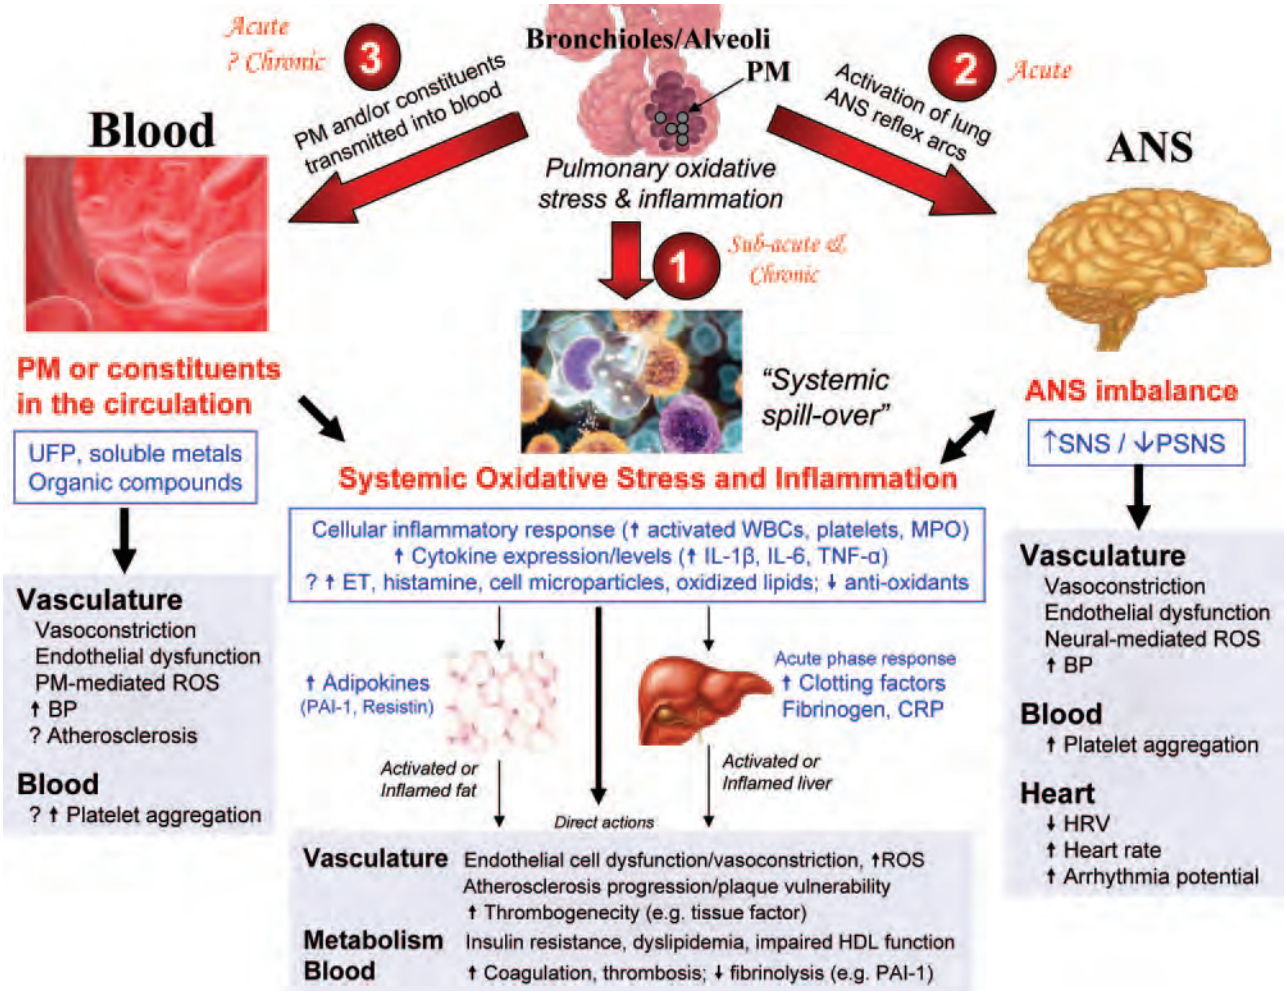

Figure 3. Biological pathways linking PM exposure with CVDs. The 3 generalized intermediary pathways and the subsequent specific biological responses that could be capable of instigating cardiovascular events are shown. MPO indicates myeloperoxidase; PAI, plasminogen activator inhibitor; PSNS, parasympathetic nervous system; SNS, sympathetic nervous system; and WBCs, white blood cells. A question mark (?) indicates a pathway/mechanism with weak or mixed evidence or a mechanism of likely yet primarily theoretical existence based on the literature.

cardiovascular effects. Studies before 2004 were reviewed previously,[1] and only some are again discussed here for contextual background. A number of new experiments have demonstrated very rapid effects of air pollution, such as vascular dysfunction, which argues for the existence of pathways that convey signals systemically within hours of PM inhalation. On the other hand, there is also support for chronic biological effects, such as the promotion of atherosclerosis. At the molecular level, persuasive evidence supports an integral role for ROS-dependent pathways at multiple stages, such as in the instigation of pulmonary oxidative stress, systemic proinflammatory responses, vascular dysfunction, and atherosclerosis. In sum, new studies continue to support the idea that inhalation of PM can instigate extrapulmonary effects on the cardiovascular system by 3 general "intermediary" pathways. These include pathway 1, the release of proinflammatory mediators (eg, cytokines, activated immune cells, or platelets) or vasculoactive molecules (eg, ET, possibly histamine, or microparticles) from lung-based cells; pathway 2, perturbation of systemic ANS balance or heart rhythm by particle interactions with lung receptors or nerves; and pathway 3, potentially the translocation of PM (ie, UFPs) or particle constituents (organic compounds, metals) into the systemic circulation (Figure 3).

Exposure Considerations

Animal and human exposure studies are discussed separately and apart from the effect of ambient PM because their methodologies and clinical relevancies vary widely. Controlled exposure studies involve exposing a subject to various size fractions of PM within a chamber connected to ambient air (concentrated or nonconcentrated) or a source of aerosolized particles. Virtual impactor systems that deliver concentrated ambient particles (CAPs) from "real-world" ambient air are a commonly used approach for mimicking exposures to higher levels of ambient particles without requiring invasive methods or the generation of artificial particles.[3] Both a strength and limitation, however, is that CAPs can vary considerably from day to day in composition. Additionally, only certain particle size ranges are typically concentrated (eg, PM from 0.1 to 2.5 μm in the fine-CAP system), whereas

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

ambient air contains a mixture of particle sizes, volatile organics, and gases that are not concentrated (and can be lowered). Potential interactions between PM and gaseous copollutants on health end points are therefore excluded, unless the latter are reintroduced in an artificial fashion. Other methods of controlled-inhalation exposures include diesel engine exhaust (diluted and aged mixtures of high numbers of fresh combustion UFPs with vapor-phase components), roadside aerosols, and wood-burning sources. Regarding animal exposures, intratracheal instillation methods may sometimes be required because of the limited availability of inhalation exposure systems. Unfortunately, particle size and surface characteristics—mostly retained in inhalation systems with fresh sources of pollution and which may be important in influencing biological effects—are likely significantly altered in instillation systems or by methods that use previously collected particulate. However, the use of carefully modeled exposures (eg, deposition calculation) and the recognition that areas of "hot spots" containing markedly higher PM levels within the lung may occur even during normal inhalation make the results of these experiments potentially relevant.[2] Further detailed discussions of exposure considerations are reviewed elsewhere.[290]

The protocol details vary considerably among the studies. Many aspects of exposure, including the duration, concentration, PM size ranges and composition, and gaseous copollutants, are important to consider. A wide variety of outcomes may be anticipated depending on the biological pathways evoked by differing exposures. Moreover, there are multiple determinants of the subsequent physiological responses, including the time frames of investigation, preexisting susceptibility, animal models, and the details of the outcomes investigated. All of these factors may explain some of the heterogeneity in the reported study results and must be taken into consideration when interpreting the findings.

Animal Exposure and Toxicological Studies

Studies that investigate the effects of exposure on susceptible animals (eg, those with preexisting cardiovascular or metabolic abnormalities) may be preferable in many circumstances because of the increasing recognition that the pathways underlying the biological effects of PM overlap (ie, modify and/or enhance) those of conventional cardiovascular risk factors. Such factors (eg, hypertension or atherosclerosis) may also be necessary or at least responsible for the evocation of a more readily observable or robust response. For example, in the context of systemic oxidative stress or inflammation, the cellular machinery for the generation of excess ROS and proinflammatory responses (eg, adhesion molecule and cytokine expression) is already primed or operational in susceptible animals.

Pulmonary Oxidative Stress and Inflammation

The molecular events responsible for triggering pulmonary oxidative stress and inflammation, along with the interactions between lung and immune cells, the inhaled PM, and the protective secretions (eg, surfactant, proteins, and antioxidants), are highly complex,[4–6] as reviewed in detail elsewhere.[290a,290b,414] In brief, size, charge, solubility, aggregation, ROS-producing potential, and chemistry play roles in determining the responses. These include the particle fate (eg, lung clearance versus retention rates), the nature of the PM-cell interactions (eg, immune versus lung cell uptake, host cell responses, and intracellular sequestration/location), and the dose (likely typically a small percentage of inhaled PM) and pathways of potential systemic transmission of PM or its constituents, such as in the circulation [free, intracellular within circulating cells, (lipo)protein-bound] or via lymphatic spread.[4,5,290a,290b] Because of their nano-scale size, UFPs may directly enter multiple lung cell types via nonphagocytic pathways and adversely affect organelles, such as mitochondria.[6,290a,290b] Larger unopsonized fine particles are more typically taken up by phagocytes through interactions with innate immunity receptors such as MARCO (macrophage receptor with collagenous structure) or other scavenger receptors.[5,290a,290b] This may in fact be a protective mechanism that sometimes prevents harmful lung inflammation. Certain particle compounds may directly generate ROS in vivo because of their surface chemistry (eg, metals, organic compounds, and semiquinones) or after bioactivation by cytochrome P450 systems (eg, polycyclic aromatic hydrocarbon conversion to quinones).[6,290a,290b] A particle surface or anions present on otherwise more inert particles may disrupt iron homeostasis in the lung and thereby also generate ROS via Fenton reactions.[291] Other PM constituents may do so indirectly by the upregulation of endogenous cellular sources (eg, nicotinamide adenine dinucleotide phosphate [NADPH]) oxidase)[292,293] or by perturbing organelle function (eg, mitochondria) by taken-up PM components.[261] Particle stimulation of irritant and afferent ANS fibers may also play a role in local and systemic oxidative stress formation.[294] Given the rich antioxidant defenses in the lung fluid, secondarily generated oxidization products of endogenous molecules (eg, oxidized phospholipids, proteins) or a reduction in endogenous antioxidants per se may be responsible at least in part for the state of oxidative stress in the lungs (along with instigating the subsequent cellular responses) rather than ROS derived directly from PM and its constituents.

Subsequent to oxidative stress, antioxidant and phase II defenses may be activated (eg, inducible nitric oxide synthase, glutathione) via transcription factor Nrf2-dependent pathways.[261] When inadequate, pathological oxidative stress can initiate a variety of pulmonary inflammatory responses. For example, ROS in the lungs has been shown to augment the signal transduction of membrane ligand (eg, epidermal growth factor by disrupting phosphatases) or pattern-recognition receptors (eg, toll-like receptors [TLR])[295–299] and/or stimulate intracellular pathways (eg, mitogen-activated protein kinases) that lead to the activation of proinflammatory transcription factors (eg, nuclear factor-$\kappa\beta$) that upregulate expression of a variety of cytokines and chemokines.[261] Alteration in lung cell redox status may itself stimulate nuclear factor-$\kappa\beta$. Biological components within coarse PM could also directly trigger inflammation (eg, nuclear factor-$\kappa\beta$ pathways) by binding to TLR2 or TLR4 receptors or other innate immune pattern-recognition receptors.[297] It is also possible that other components of metal-rich

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

PM could instigate inflammatory pathways via TLR activation directly or via the oxidation of endogenous biological compounds that then serve as TLR ligands.[300] Finally, there is some evidence that PM can activate inflammatory mitogen-activated protein kinase signaling by angiotensin II receptor–dependent pathways.[295] These inflammatory responses can also exacerbate the initial oxidative stress [eg, via upregulation of cellular NAD(P)H oxidase] and thus initiate a positive-feedback cycle.

Available studies support important contributions to pulmonary inflammation from innate immune cells such as neutrophils and macrophages (TNF-α, IL-6), as well as from the adaptive immune system, such as T cells (IL-1, IL-4, IL-6, and IL-10). Although the dominant source of cytokines likely represents the alveolar macrophages and lung epithelial cells, the role of other innate and adaptive immune cells cannot be ruled out.[299,301,302] Recently, myeloperoxidase activity was shown to increase after PM exposure in the same time course of appearance of cellular inflammation (primarily neutrophils) in the lung.[303] Gaseous components such as ozone may also amplify the toxicity of PM.[304]

Systemic Inflammation

In the context of examining the cardiovascular effects of air pollution, it is important to consider the inflammatory mediators that are released from lung cells after contact with PM, because some could conceivably spill over to the general circulation or increase liver production of acute-phase proteins (eg, CRP, fibrinogen). An increase in circulating proinflammatory mediators (eg, activated immune cells, cytokines) could thus serve as a pathway to instigate adverse effects on the heart and vasculature. Numerous experiments have demonstrated increased cellular and inflammatory cytokine content, such as IL-6, IL-1β, TNF-α, interferon-γ, and IL-8, of bronchial fluid and sometimes in circulating blood after acute exposure to a variety of pollutants.[292,305–311]

Critical roles for the elevations in systemic and pulmonary levels of IL-6 and TNF-α have been observed after PM exposure, typically coincident with pulmonary inflammation.[292,302,306,309,311–314] There is at least some evidence that the degree of pulmonary inflammation and systemic inflammation (IL-6) correlates with the elevation of systemic cytokines and systemic vascular dysfunction.[314] In a 4-week inhalation exposure to freshly generated diesel exhaust, IL-6 knockout mice did not demonstrate increased cellular inflammation or TNF-α in bronchial fluid, which implies a role for IL-6.[315] Consistent with these findings, acute intratracheal exposure to PM_{10} resulted in an increase in IL-6, TNF-α, and interferon-γ in the bronchial fluid.[316] However, in this study, IL-$6^{-/-}$ mice showed roughly the same levels of TNF-α in bronchial fluid as wild-type mice, although interferon-γ was decreased to control values.[316] The results also suggested that lung macrophages play an important role, because depletion of these cells abolished the increases in some of the cytokines and systemic cardiovascular responses. Although our understanding of the source of IL-6 and TNF-α and their involvement in the systemic inflammatory response after PM exposure remains incomplete, these and other experiments appear to suggest that at least with PM_{10} particles, alveolar macrophages play a dominant role.[309,314,316]

Among remaining uncertainties, the upstream signaling pathway responsible for the recognition of PM components that in turn produce the systemic inflammation has not been fully elucidated[317]; however, there is some evidence with other particulates and experimental models of lung injury that ROS generated by NADPH oxidase or pattern-recognition receptors may modulate some of these responses.[292,299,318] NADPH-oxidase knockout mice demonstrated significantly lower IL-6 and macrophage inflammatory protein-2 responses to collected PM than wild-type mice.[292] Extrapulmonary sources may also be involved in promulgating the systemic inflammation. $PM_{2.5}$ exposure in a model of diet-induced obesity in C57Bl/6 mice for a duration of 24 weeks resulted in elevations in TNF-α and IL-6. In addition, there were increases in circulating adipokines, such as resistin and plasminogen activator inhibitor-1.[319] The elevation in cytokines, thought to be derived from adipose sources, in addition to findings of adipose inflammation in that study, raises the possibility of additional systemic nonpulmonary sources of such cytokines.

Systemic Oxidative Stress

Numerous in vitro studies have demonstrated activation of ROS-generating pathways by PM incubation, such as NADPH oxidases, mitochondrial sources, cytochrome P450 enzymes, and endothelial nitric oxide synthase in cultured cells or in pulmonary and vascular tissue.[293,311,320–329] Similar to inflammation, the oxidative stress after PM inhalation may not always stay confined within the lungs.[330] The sources of excess ROS within cardiovascular tissue may include circulating immune cells or cytokines, depletion of defense mechanisms (eg, impaired high-density lipoprotein function), oxidation of lipoproteins or other plasma constituents,[331] activation of ANS pathways,[294] or circulating PM constituents (eg, soluble metals, organic compounds) reaching the vasculature.[261] Activation of ROS-dependent pathways modulates diverse responses with far-reaching consequences, including vascular inflammation/activation, atherosclerosis, impaired basal vasomotor balance, enhanced coagulation/thrombosis, and platelet activation.[290b]

Recent experiments have indeed confirmed the existence of footprints or markers of oxidative stress within the cardiovascular system in the in vivo context. Acute-exposure studies[332] have shown a relationship between the vascular dysfunction in spinotrapezius microvessels and the release of myeloperoxidase from leukocytes into the vasculature within only hours after the pulmonary instillation of PM.[332] Interestingly, an insoluble particle (TiO_2) induced very similar effects. More long-term studies[333] have demonstrated that 10 weeks of exposure to $PM_{2.5}$ increased superoxide production in response to angiotensin II and resulted in upregulation of NAD(P)H oxidase subunits and depletion of tetrahydrobiopterin in the vasculature. These effects had functional consequences in terms of increases in systemic vascular resistance and BP. In another investigation that involved apolipoprotein E–deficient (ApoE$^{-/-}$) fed a high-fat diet, chronic exposure

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

to $PM_{2.5}$ exacerbated vascular oxidant stress and promoted atherosclerosis progression.[334] The proatherogenic effects of ambient UFPs[331] versus $PM_{2.5}$ in genetically susceptible $ApoE^{-/-}$ mice in a mobile facility close to a Los Angeles freeway have also been compared. Exposure to UFPs resulted in an inhibition of the antiinflammatory capacity of plasma high-density lipoprotein and greater systemic oxidative stress, as evidenced by increased hepatic malondialdehyde and upregulation of Nrf2-regulated antioxidant genes.[331]

Other experiments[294] have suggested that ANS imbalance may play an important role in PM-induced cardiac oxidative stress. Pharmacological inhibition of the ANS could significantly reduce chemiluminescence in the heart after exposure.[303] More recently, an upstream modulator, the transient receptor potential vanilloid receptor-1, within the lung was identified as central to the inhaled CAP-mediated induction of cardiac chemiluminescence.[335] In these studies, capsazepine was able to abrogate ECG alterations in rats during the 5-hour exposure, which suggests that neural ANS pathways are crucial.

Thrombosis and Coagulation

Earlier studies using intratracheal instillation of high concentrations of diesel exhaust particles demonstrated the induction of lung inflammation, platelet activation, and increased peripheral vascular thrombosis in both arteries and veins after photochemical injury.[336,337] Thrombosis susceptibility was ascribed to direct passage of the instilled UFPs in the blood, because large polystyrene particles unlikely to cross the lung-blood barrier did not increase peripheral thrombosis. In a subsequent study, a persistent increase in thrombosis susceptibility to diesel exhaust particles was shown after 24 hours, an effect that was mitigated by pretreatment with sodium cromoglycate, which indicates that this response was secondary to histamine release from basophil degranulation.[338] These same effects, however, were mimicked by 400-nm polystyrene particles with a low likelihood of transgressing the pulmonary barrier, which implicates pulmonary release of histamine as a mediator of thrombosis at the later time point. Because histamine was increased in the plasma at 6 and 24 hours after exposure, and diphenhydramine mitigated diesel PM–induced thrombosis at later time points but not at 1 hour, it was hypothesized that additional direct effects of PM constituents reaching the circulation may be responsible for the earliest prothrombotic effects.[339] No increase in circulating von Willebrand factor was observed after instillation of both particles. Finally, pulmonary instillation of carbon nanotubes produced neutrophil lung influx 24 hours later. Circulating platelet-leukocyte conjugates were elevated 6 hours after exposure, whereas procoagulant microvesicular tissue factor activity and peripheral thrombotic potential were increased 24 hours later. Inhibition of P-selectin abrogated these responses, which demonstrates that rapid activation of circulating platelets by the pulmonary deposition of PM plays a vital role.[340] This series of studies suggests that release of lung cell–derived mediators (eg, histamine) after several hours along with the more rapid activation of circulating platelets by lung inflammation via P-selectin–dependent processes may mediate distant system prothrombotic effects without necessarily inducing systemic endothelial damage.

In a study using C57BL/6J mice, intratracheal PM_{10} particles rich in transition metals decreased bleeding, prothrombin, and activated partial thromboplastin times and enhanced the levels of several coagulation factors as well as thrombosis times in response to experimental $FeCl_3$ injury.[316] This prothrombotic effect was mitigated in IL-$6^{-/-}$ and macrophage-depleted mice, which suggests that IL-6, lung macrophages, and pulmonary inflammation are necessary initial steps. It is possible, however, that coarse-particle components (eg, endotoxin) could have been important mechanistically via TLR activation. The effect of fine PM or UFPs per se requires more investigation. Chronic ambient exposure to $PM_{2.5}$ has also been shown to increase tissue factor expression in macrophages and smooth muscle cells in atherosclerotic lesions. Complementary in vitro studies with cultured human smooth muscle cells and monocytes demonstrate dose-dependent increases in tissue factor in response to collected ambient particles.[341] Other findings also support potential procoagulant and thrombotic effects of PM.[342,343] These collective studies suggest that both short- and long-term PM inhalation can enhance thrombotic and coagulation tendencies, potentially via increases in circulating histamine and inflammatory cytokines and/or activated white cells and platelets. The plausibility of these pathways is supported by the well-recognized cross talk between inflammation and thrombosis.[344] Potential additional roles for UFPs or soluble constituents that reach the circulation and directly enhance platelet aggregation or systemic oxidative stress (thus activating the endothelium and blunting platelet-derived nitric oxide) require more investigation.

Systemic and Pulmonary Hypertension

Early animal studies suggested small or inconsistent effects of PM on BP,[345–347] sometimes dependent on the season[348] of exposures. A potential explanation may be variations in experimental protocols, including differences in the delivery, duration, and composition of exposure and the methods used to measure BP. Moreover, PM by itself may represent a relatively weak stimulus but may act more robustly in concert with other predisposing factors to affect BP. Sun et al[333] recently demonstrated a significant interactive effect of fine-CAP exposure with the vasoconstrictor angiotensin II in rats. Preexposure to $PM_{2.5}$ for a 10-week period resulted in enhancement of its prohypertensive response measured continuously by intra-arterial radiotelemetry. The exaggerated BP elevation was accompanied by endothelial dysfunction, including blunted endothelium-dependent vasodilation and enhanced vasoconstrictor reactivity, along with upregulation of NAPDH oxidase and Rho-kinase–signaling pathways. In vitro exposure to UFPs and $PM_{2.5}$ was also associated with an increase in Rho-kinase activity, phosphorylation of myosin light chain, and myosin phosphatase target subunit. Pretreatment with the nonspecific antioxidant *N*-acetylcysteine and Rho-kinase inhibitors prevented these responses, which suggests an ROS-mediated mechanism for particle-mediated effects on vascular smooth muscle constriction. Further

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

studies corroborated the role of exaggerated Rho-kinase pathway activity in potentiating the hypertensive response to angiotensin II in mice exposed to $PM_{2.5}$.[349] Moreover, particle exposure augmented angiotensin-mediated cardiac hypertrophy and collagen deposition. Blockade of Rho-kinase abolished these effects. These responses suggest that chronic $PM_{2.5}$ exposure disrupts normal vascular homeostasis and vasoactive mediator balance through ROS-dependent mechanisms in a manner that sensitizes the vessel toward vasoconstrictors. Activation of RhoA/Rho-kinase signaling pathways appears to play an important mechanistic role.

In conscious canines with implanted BP catheters, systemic arterial BP increased and baroreceptor sensitivity was rapidly altered over a few hours during CAP exposure.[350] Interestingly, α-adrenergic antagonism abrogated the responses. The findings support a mechanistic role for acute activation of the sympathetic nervous system by inhaled particles. In a study with Wistar-Kyoto male rats, CAP exposure for 4 days upregulated ET-A receptor expression in the heart. This alteration was also weakly correlated with an increase in BP, which suggests a role for enhance ET activity.[351] PM has also been demonstrated to alter the release of ET-1 and ET-3 from the lungs.[352] Elevation in pulmonary vascular resistance and pulmonary arterial pressure, which suggests constriction of the pulmonary vessels, has also been demonstrated in response to respirable carbon black particles.[353] Recently, ultrafine carbon particles were shown to increase BP in spontaneously hypertensive rats 1 to 3 days after a 24-hour exposure.[354] This response occurred concomitant with increased ET-1 messenger ribonucleic acid levels in lung tissue and small elevations in plasma renin concentration and angiotensin I and II in the systemic circulation. These findings further support the idea that ET may play a role in cardiovascular responses to PM exposure and suggest that activation of the renin-angiotensin system may also be involved. It is not clear whether the elevated circulating ET levels reflect increased release from the lungs and whether this mediates a systemic vasoconstrictor response. Alternatively, the increase may be more indicative of enhanced vascular tissue activity of these systems. Longer-term exposures of carbon black for 4 weeks in Sprague-Dawley rats has also been shown to significantly increase systolic BP concomitant with increases in serum levels of IL-6 and CRP.[355]

Finally, in vitro exposure to soluble and insoluble components of UFPs induces constriction in isolated pulmonary arterial rings and activates intracellular signaling pathways such as phosphorylation of extracellular signal–regulated kinase-1/2 and p38 mitogen-activated protein kinase in pulmonary endothelial cells. These effects were antagonized by losartan, and several metal components (copper and zinc) could replicate the responses.[295] This suggests a possible role for activation of angiotensin II receptor pathways relevant for the maintenance of vasomotor tone and smooth muscle constriction after inhalation of metal constituents within PM.

In sum, the studies demonstrate that long-term PM exposures over a period of weeks are capable of enhancing vasoconstrictive responsiveness of the vasculature (eg, increased Rho-kinase activity and reduced nitric oxide bioavailability) by inflammatory and ROS-dependent cell-signaling pathways. Shorter-term exposures over several hours to days may lead to vasoconstriction and increased pulmonary and systemic BP by pathways dependent on enhanced ET or angiotensin II signaling. Lung cells may release ET into the systemic circulation and thus increase its systemic activity, or the vascular ET system may be relatively upregulated because of increased ROS or reduced nitric oxide. Activation of the renin-angiotensin system may also occur because of systemic oxidative stress or inflammation or as a consequence of ANS imbalance. The very acute increase in BP that occurs concomitant with the inhalation of particles or within only minutes to hours after exposure appears to be mediated by autonomic imbalance that favors a relative activation of the sympathetic nervous system. No study has evaluated the effect of air pollution on renal sodium handling or long-term pressure natriuresis mechanisms, which are fundamental to the generation of chronic hypertension.

Vascular Dysfunction and Atherosclerosis

Many early experiments demonstrated the capacity of PM constituents to blunt nitric oxide–dependent dilation and enhance vasoconstrictor tone in ex vivo vascular studies because of excess ROS formation.[1] The first in vivo experiment demonstrated the proatherosclerotic actions of intratracheal PM_{10} instillation.[356] More recently, the pulmonary instillation of several different PM types was shown to rapidly impair microvascular endothelium-dependent vasodilation within days, likely by proinflammatory or ROS-dependent mechanisms (eg, myeloperoxidase).[332] Several animal studies have now demonstrated that long-term exposure to ambient $PM_{2.5}$, by use of ambient-exposure facilities without direct pulmonary instillation, not only causes endothelial dysfunction but also accelerates the progression of atherosclerosis. Sun et al[334] demonstrated that exposure of atherosclerosis-prone $ApoE^{-/-}$ mice to environmentally relevant levels of CAP, derived from regional northeastern $PM_{2.5}$, for 6 months in conjunction with a high-fat chow diet potentiated plaque development and heightened vascular inflammation (CD68+ macrophage infiltration and inducible nitric oxide synthase expression) and oxidant stress. The atherosclerotic plaque progression was also accompanied by alterations in vasomotor tone, including decreased endothelium-dependent vasodilation and heightened vasoconstriction to adrenergic stimuli. Importantly, the normalized average $PM_{2.5}$ concentration over the entire period was 15.2 $\mu g/m^3$, which approximates the annual NAAQS. Similar findings were reported in other chronic CAP exposures that involved an $ApoE^{-/-}$ model.[357] However, exposures to a double-knockout model of ApoE-deficient and low-density lipoprotein receptor–deficient mice increased plaque cellularity, reflective of inflammation, but did not enhance plaque burden. It is possible that the atherosclerotic severity of this phenotype precluded the observation of more subtle effects of CAP exposures.

Intratracheal instillation of UFP can acutely impair aortic endothelium-dependent vasodilation.[358] Moreover, repeated 10-week-long endotracheal dispersion of UFP carbon black increased atherosclerosis in low-density lipoprotein receptor–

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

knockout mice.[359] This occurred without evidence of systemic translocation of particles into the cardiovascular tissues. UFP inhalation by use of exposure facilities has also recently been shown to augment atherosclerosis, perhaps to a greater degree than $PM_{2.5}$. When investigating the effects of different PM size fractions, Araujo et al[331] compared the proatherogenic potential of exposure over 40 days to ambient particles <0.18 μm versus $PM_{2.5}$ in $ApoE^{-/-}$ mice. UFPs caused more adverse cardiovascular responses (eg, systemic oxidative stress, impaired high-density lipoprotein function) and greater potency in accelerating atherosclerotic lesion formation, although $PM_{2.5}$ did demonstrate qualitatively similar effects. Recent studies have also demonstrated that PM exposure likely promulgates systemic atherosclerosis by mechanisms that overlap those of other conventional cardiovascular risk factors.[360] Intratracheal instillation of PM_{10} particles caused a rapid impairment in endothelium-dependent vasodilation, stimulation of bone marrow–derived cells, and increased migration of monocytes into atherosclerotic plaques.[361,362] Systemic inflammation (IL-6) was also related to the degree of endothelial dysfunction.[314] Finally, the most compelling evidence for rapid impairment in nitric oxide bioavailability being directly involved in the origin of PM-induced endothelial dysfunction was demonstrated recently. Both fine-PM and UFM inhalation for only a few hours in normal rats blunted agonist-stimulated nitric oxide production within the microvasculature, measured by direct electrochemical sensors, concomitant with an observed impairment in vasomotor relaxation. Inhibition of myeloperoxidase or NADP(H) oxidase partially restored normal nitric oxide bioavailability and endothelial function, which suggests a role of activation of these endogenous radical-generating enzymes in this biological response.[363]

Potentially relevant adverse vascular effects of nonparticulate PM components should not be discounted. There may also exist some synergy between vapor phase, gas, and particle constituents in relation to instigation of cardiovascular responses. Recently,[364] it was demonstrated in $apoE^{-/-}$ mice that whole gasoline engine exhaust over 1 or 7 days increased vascular messenger ribonucleic acid expression of matrix metalloproteinase (MMP)-2 and MMP-9. Levels of ET-1 and ROS were similarly increased. The vascular ROS and MMP-2 elevations were attenuated by tempol. Endothelial receptor antagonism ameliorated the vascular expression of MMP-2, MMP-9, and ROS. In separate experiments, diesel exhaust exposure to rats for 5 hours augmented ET-induced vasoconstriction, potentially via a blunting of ET-B–induced nitric oxide release.[365] The findings suggest that exposure to a fresh mixture of PM, gases, and vapors may play a role in rapidly triggering atherosclerotic plaque vulnerability via ROS and ET-dependent upregulation of MMP levels.

Some studies suggest that predisposed animals may be more susceptible to air pollution–mediated vascular dysfunction. Diesel exhaust particles delivered by intraperitoneal injection impaired nitric oxide–dependent vasodilation only in $apoE^{-/-}$ mice with atherosclerosis and not in healthy control animals.[366] Aortas from prediabetic rats were found to be more susceptible to repeated exposures to oil combustion particles in causing noradrenergic-mediated constriction and impaired endothelium-dependent vasodilation.[367]

Taken together, the available studies suggest that short- and long-term particle exposures (including PM_{10}, $PM_{2.5}$, and UFP) can impair conduit and resistance arterial endothelium-dependent vasodilation. Chronic exposures have been shown to be capable of promoting atherosclerosis progression and enhancing plaque vulnerability. The underlying mechanisms likely involve vascular sequelae of systemic inflammation (due to interactions with innate immune cells and cytokines) or exaggerated oxidative stress pathways. Excess vascular ROS and inflammation will impair endogenous vasodilator bioavailability (eg, nitric oxide), enhance vasoconstrictor tone (eg, ET), and chronically activate multiple intracellular pathways that promote atherosclerosis.[368–370]

Heart Rate Variability

Some of the earliest indications of systemic effects of PM came from ECG studies in rats.[371] In general, reductions in several measures of HRV have been shown.[372–376] Most of the recent research has focused on exploring the roles of susceptibility and exposure characteristics. Decreases in heart rate and HRV indices have been reported to be pronounced in senescent mice, which indicates that aging may be a susceptibility factor.[353] Using an anesthetized model of postinfarction myocardium sensitivity, Wellenius and colleagues[377] did not demonstrate an effect of 1 hour of CAP exposure on heart rate or spontaneous ventricular arrhythmias. In contrast, in a post-MI heart failure model in Sprague-Dawley rats, diesel exhaust emissions reduced HRV in both healthy and heart failure groups and increased the incidence of premature ventricular contractions. Studies in mice have also indicated a potential role for transition metals and nickel in HRV alterations[376] and provide initial clues on the PM components that could influence autonomic tone.[48]

Some beginning insight into the neural pathways involved has been reported recently. PM-induced ECG changes in rats were shown to be prevented by inhibiting the transient receptor potential vanilloid receptor in the lungs. This suggests that the relevant neural mechanism that leads to alterations in HRV or heart rhythm may be induced by activation of receptor-mediated autonomic reflexes in the lung.[335] Circulating particle constituents or inflammatory mediators interacting with myocardial ion channels or electrophysiology did not appear to be a pertinent mechanism, at least in these studies.[335] However, it is unknown whether similar mechanisms can account for the HRV changes observed in humans, and a more detailed understanding of the anatomic pathways involved is required. Finally, it remains unclear whether the changes in cardiac HRV are actually caused by or merely illustrate an underlying alteration in ANS balance. Experiments that clearly define the direct contribution of sympathetic and parasympathetic nervous system activities (eg, microneurography, norepinephrine spillover rates, or autonomic receptor or ganglionic blockade) are needed.

MI and Arrhythmia

PM exposure can increase experimental infarct size and potentiate myocardial ischemia and arrhythmias in experi-

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

mental MI models. Relatively high concentrations of intratracheal UFP instillation induced pulmonary inflammation and doubled MI size in mice.[358] Conscious dogs exposed to fine CAP for several days experienced greater ST-segment changes during transient coronary artery occlusion.[378] These studies suggested that particulate-related changes in myocardial blood flow may be responsible, a hypothesis recently supported by experiments in chronically instrumented dogs exposed to fine CAP before transient occlusion of the left anterior descending artery. PM exposure was associated with a small but significant decrease in total myocardial flow, especially in the ischemic zone, and increases in coronary vascular resistance without an alteration in rate-pressure product.[379] The abnormalities were inversely related to PM mass, particle number, and black carbon concentration.

Exposure to residual oil fly ash increases arrhythmia frequency in rats with preexisting premature ventricular complexes, which suggests that PM sensitizes ischemic myocardium to abnormal automaticity[372]; however, CAP had no effect in rats.[380] Nevertheless, the data suggest that PM exposure may potentially be capable increasing the sensitivity of the myocardium to ischemia, likely by impairing myocardial blood flow and perfusion. In theory, this could play a role in enhancing the propensity for ventricular arrhythmias.

Insulin Resistance

Recently, Sun et al[319] exposed C57BL/6 mice fed high-fat chow to fine CAP or filtered air for 24 weeks. Mice exposed to $PM_{2.5}$ exhibited marked worsening of whole-body insulin resistance, systemic inflammation (increased IL-6 and TNF-α), and higher levels of adipokines, such as resistin and plasminogen activator inhibitor-1. $PM_{2.5}$ increased visceral adiposity and inflammation ($F4/80^+$ cells), with stromal vascular cells expressing higher TNF-α and IL-6 and lower IL-10 levels. Exposure also induced insulin-signaling abnormalities and reduced phosphorylation of Akt and endothelial nitric oxide synthase in aortic tissue, accompanied by abnormalities in vascular relaxation to insulin. Additionally, there was evidence that $PM_{2.5}$ exaggerated adhesion of monocytes in mesenteric microvessels, culminating in accumulation in visceral adipose. These intriguing findings suggest that longer-term exposure to PM air pollution may promote the chronic development of insulin resistance, obesity, and the metabolic syndrome.

Controlled-Exposure Studies in Humans

Several new human exposure studies have been published, a few of which have even included patients with CVD or risk factors. Similar to the animal studies, large variations among the exposure protocols, measured outcomes, and subject susceptibilities likely explain much of the differences among findings and must be considered when interpreting the results.

Systemic Inflammation

Controlled human exposure studies have measured the effects on circulating inflammatory markers such as CRP, IL-6, and TNF-α. In many of these single-episode short-term exposures, no overt changes in plasma cytokine levels were observed after CAP[381–383] or diesel exhaust.[345,384–386] Similarly, CRP levels have not consistently been found to increase in the time frame and context of most of these studies.[313,384–386]

However, there have also been some positive findings. Increases in IL-6[313] and TNF-α 24 hours after exposure to diesel exhaust in healthy adults have been reported. High levels of ambient particles can stimulate the bone marrow to enhance the release of neutrophils, band cells, and monocytes into the circulation, which causes a cellular inflammatory response.[387,388] Some controlled-exposure studies corroborate the existence of a cellular proinflammatory response that manifests as increases in circulating white blood cell or immune cell counts. In 1 study, increased peripheral basophils in healthy older adults were noted 4 hours after a 2-hour exposure to fine CAP.[389] In a similar study, increased white blood cell counts were observed in healthy young adults 12 hours after exposure.[381] Recently, investigators observed an increased in total white blood cell and neutrophil levels immediately after a 2-hour exposure to CAP in downtown Toronto, Ontario, Canada.[390] Conversely, decreases in blood monocytes, basophils, eosinophils, and CD54 and CD18 adhesion molecule expression on monocytes after exposure to ultrafine carbon (10 to 50 $\mu g/m^3$) among exercising asthmatic individuals and healthy adults have also been reported.[391] The authors suggested in the latter study that these results may represent the sequestration of these cells in tissue compartments such as the lung or vasculature, where there may be selective expression of the corresponding receptors for these ligands.[362] However, other recent human clinical studies have found no association between peripheral blood cell counts and exposure to fine PM or UFPs such as zinc oxide,[392] ultrafine carbon,[393] or diesel exhaust.[313,384,385]

More subtle, yet physiologically relevant or functional proinflammatory changes may be overlooked by the measurement of circulating cytokines or cell counts alone in human studies. Peretz et al[394] recently evaluated gene expression using an expression array in monocytes after 2 hours of exposure to diesel exhaust. Although initially a small study, 10 genes involved in the inflammatory response were modulated in response to exposure (8 upregulated, 2 downregulated). These findings will need to be reproduced in larger studies and raise the possibility that functional changes in inflammatory cells may occur without discernible changes in their levels in the peripheral circulation.[394]

In sum, the findings from controlled human exposures do not demonstrate a robust inflammatory response; however, they have been limited by the fact that they are, by necessity, of short duration and relatively low concentration. Additionally, the results do not preclude an effect of higher exposures, the presence of more subtle responses, or alterations in other cellular inflammatory pathways not measurable by circulating markers.

Systemic Oxidative Stress

The demonstration of systemic oxidative stress is difficult in human studies. Nonetheless, a few studies have reported positive findings. These include an increase in urinary excre-

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

tion of free 8-iso-prostaglandin-2α among healthy adults after a 4-hour exposure to concentrated wood smoke[395] and an increase in plasma antioxidant capacity 24 hours after a 1-hour exposure to diesel exhaust in a group of healthy volunteers.[313] The investigators speculated that systemic oxidative stress after exposure may have been responsible for this upregulation in antioxidant defense.[313] Other investigators[394] have observed significant differences in expression of genes involved in oxidative stress pathways due to diesel exhaust exposure. Bräuner et al[167] recently investigated the effect of ultrafine traffic particles on oxidative stress–induced damage to DNA in healthy young adults exposed to low concentrations of ambient urban particles ($PM_{2.5}$ and $PM_{10-2.5}$ mass of 9.7 and 12.6 $\mu g/m^3$, respectively) in an exposure chamber above a busy road with high traffic density. The authors observed increased levels of DNA strand breaks and formamidopyrimidine-DNA glycosylase sites in monocytes after exposure to PM but no changes in the DNA repair enzyme 7,8-dihydro-8-oxoguanine-DNA glycosylase. Similar to their previous findings with ambient levels,[168] the results suggest that short-term exposure to UFPs may result in damage to DNA. This may occur through oxidative stress pathways, although there was no increase in messenger ribonucleic acid levels in heme oxygenase-1, a gene known to be regulated by Nrf2, a transcription factor regulated by oxidative stress.[396] Moreover, more recent observations by the same investigators failed to demonstrate significant biomarker signals for lipid or protein oxidative damage after similar near-roadway exposures.[178] Although not entirely consistent, the available studies demonstrate that acute exposure to PM, perhaps even at ambient levels, may be capable of inducing acute systemic oxidative stress in human subjects under certain circumstances. The assays used to assess the footprint of systemic "oxidative stress" or damage may also play a significant role in the results.

Thrombosis and Coagulation

Several new studies of controlled human exposure have evaluated the effects of PM on hemostatic markers (eg, factor VII, fibrinogen, platelet count, D-dimer, and von Willebrand factor). Although some of these studies have not observed changes after acute exposures,[392] others have reported increases in fibrinogen levels at 8 to 24 hours after exposure to CAP.[381,397] Mills and colleagues[384,385] recently demonstrated a significant effect of diesel exhaust on fibrinolytic function in response to intermittent exercise both in healthy men and in men with coronary heart disease. In both groups of volunteers, bradykinin-induced release of tissue plasminogen activator was observed to decrease compared with filtered air at 6 hours after exposure to diesel exhaust. These perturbations in tissue plasminogen activator release did not persist 24 hours after exposure.[313] In a randomized, controlled crossover study involving "at-risk" metabolic syndrome patients, no changes in plasminogen activator inhibitor-1 were noted over a 24-hour duration; paradoxically, a decrease in von Willebrand factor was noted in this study.[398] In a similar experiment conducted in healthy adults, diesel exhaust had no effect on D-dimer, von Willebrand factor, CRP, or platelet counts compared with filtered air up to 22 hours after exposure.[386] Other investigators[395] recently evaluated the effect of wood smoke on markers of coagulation, inflammation, and lipid peroxidation in young healthy subjects. Serum amyloid A and the ratio of factor VIII to von Willebrand factor, an indicator of an increased risk of venous thromboembolism, were increased at 4 hours after exposure.[395] Samet et al[383] reported an association between various coagulation markers and exposure to ultrafine, fine, and thoracic coarse CAP among healthy young adults. Although exposure to coarse CAP did not result in significant changes in hemostatic variables, the overall trend suggested a prothrombotic effect. Exposure to UFPs increased D-dimer levels, whereas fine-CAP effects tended to increase fibrinogen, similar to previously reported findings.[381]

The measurement of blood levels of coagulation factors or biomarkers of thrombosis could potentially miss a relevant biological effect at the vascular wall. Recently, ex vivo thrombus formation was assessed by use of the Badimon chamber after controlled exposures to dilute diesel exhaust in healthy volunteers.[399] This protocol measures thrombus formation in native (nonanticoagulated) whole blood triggered by exposure to a physiologically relevant substrate, under flow conditions that mimic those found in diseased coronary arteries. It may therefore provide a superior estimate of actual in vivo conditions related to thrombosis potential. Interestingly, dilute diesel exhaust exposure increased thrombus formation within 2 hours, in association with increased platelet activation (ie, increased circulating platelet-monocyte aggregates and soluble CD40 ligand). Taken together, these new studies have provided additional evidence that short-term exposure to PM at near-ambient levels may have small yet potentially significant effects on hemostasis in humans. Whether direct interactions of circulating PM constituents with platelets, activation of platelets due to lung inflammation or secondary to elevated systemic cytokine levels, or an increase in procoagulant factors (eg, fibrinogen) as an acute-phase response to inflammation (or a combination of these pathways) is responsible warrants attention in future studies.

Arterial BP

Although several studies have evaluated the BP response to acute exposures, many inconsistencies in results have been reported.[400] This must be considered in the context that BP was not the primary outcome of interest in most studies, nor was it typically assessed with adequate sophistication. In one of the earliest studies, $PM_{2.5}$ increased systolic BP in healthy subjects but decreased it in asthmatic individuals.[401] Three other controlled studies did not report changes among healthy adults.[345,402,403] However, in a more detailed reanalysis of the changes in BP during the actual period of exposure to CAP plus ozone, Urch et al[404] found a significant increase in diastolic BP of 6 mm Hg. The magnitude of response was associated with the concentration of organic carbon within $PM_{2.5}$.[405] Recent follow-up studies redemonstrated an acute prohypertensive response during the inhalation of CAP in 2 separate cities.[390] The $PM_{2.5}$ mass during exposure and decreases in several HRV metrics were associated with the

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

magnitude of the short-lived diastolic BP elevation. This suggested that the most plausible mechanism for this acute response was CAP-induced ANS imbalance that favored sympathetic over parasympathetic cardiovascular tone. Whether this reaction occurred because of a generalized stress response, as a consequence of specific soluble PM constituents directly altering central nervous system activity, or via altered ANS reflex arcs due to the interaction of inhaled particles with lung receptors/nerve endings remains to be elucidated.

The effect of inhaled particulates on BP has also been investigated in several other recent controlled human exposure studies. Two new studies assessed BP changes after a 1-hour exposure to diesel exhaust. Mills et al[384] found a 6-mm Hg increase in diastolic BP 2 hours after exposure, which was of marginal statistical significance ($P=0.08$); however, this trend did not persist for 24 hours,[384] nor was it found among patients with coronary artery disease.[385] The available data to date suggest that short-term exposure to $PM_{2.5}$ or diesel exhaust is capable in certain circumstances of rapidly raising BP. The most consistent and largest effects were seen concomitant with the inhalation of particles. Thus far, the most likely mechanism for such rapid hemodynamic responses appears to be ANS imbalance. However, it is possible that reductions in nitric oxide bioavailability that modulate basal arterial tone toward vasoconstriction or increases in ET among other hemodynamically active molecules (eg, angiotensin II) also play a role in some circumstances.

Vascular Dysfunction

The first controlled human exposure study related to vascular function reported that CAP plus ozone exposure caused acute conduit arterial vasoconstriction in healthy adults.[1] Endothelium-dependent and -independent vasodilation remained intact. Recent follow-up experiments determined that $PM_{2.5}$, not ozone, was responsible for the adverse vascular effects. However, in these subsequent and larger experiments, fine-CAP exposure did prove capable of diminishing conduit artery endothelium-dependent vasodilation 24 hours (but not immediately) after exposure.[390] Postexposure $PM_{2.5}$ mass and TNF-α level were both associated with the degree of endothelial dysfunction, which suggests that systemic inflammation induced by higher levels of particles was likely responsible. Finally, the CAP-induced endothelial dysfunction occurred during exposures in Toronto, Canada, but not Ann Arbor, Mich, which suggests that the composition of the particles is probably an important determinant of the vascular responses.

An acute alteration in vascular function/tone after short-term controlled PM air pollution exposure was corroborated recently.[406] In 27 adults (10 healthy adults and 17 with the metabolic syndrome), a 2-hour exposure to dilute diesel exhaust caused a dose-dependent constriction of the brachial artery and elevation in plasma ET level without impairing endothelium-dependent vasodilation. Contrary to the hypothesis that metabolic syndrome patients would show greater effects, vasoconstriction was greater in magnitude among the healthy participants. In an additional study, 2-hour exposure to UFPs composed of elemental carbon impaired peak forearm blood flow response to ischemia 3.5 hours later. There were no other vascular changes or alterations at other time points. BP was also not affected.[407]

Several recent studies have also shown that dilute diesel exhaust can impair peripheral resistance vessel responses to acetylcholine, bradykinin, and nitroprusside 6 hours after exposure.[384] The blunted responses to acetylcholine persisted for 24 hours in healthy adults.[313] In contrast, bradykinin and sodium nitroprusside–mediated vasodilation and bradykinin-induced acute plasma tissue plasminogen activator release were not altered 24 hours later. In subsequent studies, patients with stable coronary artery disease exposed to dilute diesel exhaust for 1 hour during intermittent exercise demonstrated reduced bradykinin-mediated tissue plasminogen activator release; however, microvascular endothelial function was not impaired.[385] This may be related to some degree of preexisting endothelial dysfunction in these patients. However, exercise-induced ST-segment depression and ischemic burden were significantly greater during diesel compared with filtered air exposure. These important findings experimentally highlight that PM air pollution exposure can trigger, or augment existing, myocardial ischemia extremely rapidly (in fact, concomitant with exposure). Reduced coronary flow reserve (that was not observed or resolved at the time of the postexposure brachial artery studies) due to rapid alterations in coronary microvascular function may have contributed to the acute myocardial ischemia. Alternatively, acute ANS imbalance induced by diesel exhaust inhalation may have acutely altered coronary tone and impaired myocardial perfusion.

In a study that exposed healthy young adults to 100 $\mu g/m^3$ of diesel exhaust for 2 hours,[364] it was recently demonstrated that this air pollution mixture acutely raised plasma ET-1 and MMP-9 expression and activity within 30 minutes. These results corroborate the animal data that even short-term exposures can rapidly alter factors, such as MMP activity, that are mechanistically linked with causing atherosclerotic plaque disruption (and thus acute MI). The increase in ET levels also corroborates previous studies[406] that showed that diesel exhaust can acutely affect important endogenous regulators of vasomotor tone.

Controlled air pollution exposures have not always been shown to impair endothelial function or vasomotor tone. Despite an increase in exhaled 8-isoprostane concentrations that suggested pulmonary oxidative stress, fine CAP did not affect brachial flow–mediated dilation or basal diameter in northern Scotland exposures.[382] However, the $PM_{2.5}$ consisted of relatively inert ambient sea-salt particles and was extremely low in combustion-derived sources. This is in contrast to the particle chemistry in the investigators' previous diesel exposure studies that showed positive findings.[408,409] Moreover, 24-hour exposure to ambient pollution shunted into a chamber next to a busy street did not impair microvascular endothelial function in 29 healthy subjects, as assessed by digital tonometry.[178] This exposure to near-roadway ambient air, which consisted of ambient UFP and $PM_{2.5}$, did not alter biomarkers of inflammation, hemostasis,

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

or protein and lipid oxidation. The authors speculated that the relatively low concentrations of UFP numbers and PM mass or the young, healthy status of the subjects could explain the null findings. Taken together, these studies suggest that brief PM exposure can trigger conduit arterial vasoconstriction, possibly in relation to increased ET activity or augmented sympathetic ANS tone. Under certain circumstances, conduit and resistance arteriole endothelium-dependent vasodilation can also be impaired within a few hours. This abnormality is more likely due to reduced nitric oxide bioavailability as a consequence of systemic proinflammatory and oxidative responses; however, alternative mechanisms and endogenous vasoactive pathways have not been fully explored. It is also apparent that the composition, source, and concentration of pollution, along with the susceptibility of the human subjects, play important roles in determining the vascular effects of acute air pollution exposure.

Heart Rate Variability

The results of several new controlled human exposure studies provide limited evidence to suggest that acute exposure to near-ambient levels of PM may be associated with small changes in HRV. There are at least 4 studies to support this. In the first study, healthy elderly individuals experienced significant decreases in HRV immediately after exposure.[233] Some of these changes persisted for at least 24 hours. Gong et al[410] studied healthy and asthmatic adults exposed to coarse CAPs with intermittent exercise. HRV was not affected immediately after the exposure but decreased in both groups at 4 and 22 hours after the end of the exposure; greater responses were observed in nonasthmatic individuals.[410] In another study, healthy elderly subjects and patients with chronic obstructive pulmonary disease were exposed to approximately 200 $\mu g/m^3$ CAP and filtered air for 2 hours with intermittent mild exercise. HRV over multihour intervals was lower after CAP than after filtered air in healthy elderly subjects but not in subjects with lung disease. A significant negative effect of CAP on ectopic heartbeats during or after CAP exposure relative to filtered air was noted in the healthy subjects, whereas the group with pulmonary disease experienced an improvement during or after CAP relative to filtered air.[389] Other investigators recently compared the effects of 2-hour exposures with intermittent exercise to ultrafine (average concentration 47 $\mu g/m^3$), fine (average concentration 120 $\mu g/m^3$), and coarse (average concentration 89 $\mu g/m^3$) CAP among healthy subjects.[383] In both the ultrafine and coarse studies, a crossover design was used in which each subject was exposed to both PM and filtered air. In the case of the fine-PM study, subjects did not serve as their own control but were exposed to either PM or filtered air. Thoracic coarse fraction CAP produced a statistically significant decrease in the standard deviation of normal-to-normal heart rate 20 hours after exposure compared with filtered air. No statistically significant effects on HRV were observed after exposure to UFPs as measured during controlled 5-minute intervals. However, the authors did observe a significant decrease in the standard deviation of normal-to-normal heart rate after exposure to UFPs based on an analysis of the 24-hour measurements. No differences were reported in HRV with fine-PM exposures. Although some controlled-exposure studies have reported either no acute changes[390] or, on occasion, increases in HRV metrics in subsets of individuals,[208,393,401] these studies generally demonstrate that acute PM exposure is capable of reducing HRV. More consistent reductions have been found among older adults (compared with younger subjects or those with lung diseases, who show mixed responses) and perhaps with exposures to larger particles.[233,389] Whether pulmonary ANS reflex arcs are activated by the deposition of PM within the lung or whether other pathways are responsible for these physiological changes in human exposure studies requires more investigation.

Table 7. Summary of Level of Evidence Supporting Global Biological Pathways and Specific Mechanisms Whereby $PM_{2.5}$, Traffic-Related, or Combustion-Related Air Pollution Exposure Can Affect the Cardiovascular System

	Animal Studies	Human Studies
General "intermediary" pathways whereby PM inhalation can instigate extrapulmonary effects on the cardiovascular system		
Pathway 1: Instigation of systemic proinflammatory responses	↑ ↑ ↑	↑ ↑ ↑
Pathway 2: Alterations in systemic ANS balance/activity	↑	↑ ↑
Pathway 3: PM and/or associated constituents directly reaching the systemic circulation	↑	↑
Specific biological mechanisms directly responsible for triggering cardiovascular events		
Vascular dysfunction or vasoconstriction	↑ ↑ ↑	↑ ↑
Enhanced thrombosis or coagulation potential	↑ ↑	↑ ↑
Elevated arterial BP	↑ ↑	↑ ↑
Enhanced atherosclerosis or plaque vulnerability	↑ ↑	↑
Arrhythmias	↑	↑

The arrows are not indicators of the relative size of the association but represent a qualitative assessment based on the consensus of the writing group of the strength of the mechanistic evidence based on the number and/or quality, as well as the consistency, of the relevant studies.

↑ ↑ ↑ Indicates strong overall mechanistic evidence.

↑ ↑ Indicates moderate overall mechanistic evidence.

↑ Indicates some but limited or weak available mechanistic evidence.

Blank indicates lack of evidence.

Evidence Summary and Contextual Framework for Biological Mechanisms

Table 7 provides an outline of the level of evidence supporting the generalized intermediary pathways and specific mechanisms whereby PM exposures can be capable of eliciting

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

cardiovascular events. At the molecular level, oxidative stress as a critically important cause and consequence of PM-mediated cardiovascular effects has a sound experimental basis.[261,290b,294,319,333,334,345–349,351,361–364,411] At the integrated physiological level, the collective body of evidence continues to support the existence of 3 general pathways (Figure 3). Some of these responses, such as systemic inflammation (via pathway 1), likely require antecedent pulmonary oxidative stress or inflammation in order to be initiated. Others, including ANS imbalance (via pathway 2) and PM or its constituents reaching the systemic circulation (via pathway 3), may not. Although PM-associated metals[412] and certain UFPs[261,413–415] might be capable of translocating into the blood stream, some studies have been negative in this regard.[355,416] Many issues related to this pathway are controversial and require resolution.[416] These include the relevance of the dosages delivered to cardiovascular organs, the consequences of particle constituent modifications after interactions with lung tissue/fluids and plasma components, the means of transport within the circulation (eg, protein bound or within cells),[417] and the time course and ultimate sites of PM sequestration. It is also possible that increases in some vasoactive mediators or molecules with adverse effects on cardiovascular tissue, such as ET-1,[351–354] may occur in the lung and systemic circulation without the need for antecedent lung inflammation. Moreover, the 3 general pathways represent a simplification of complicated biological processes. They may not be mutually exclusive, may overlap temporally, and likely exhibit synergies in causing manifest cardiovascular disease events. Many of the biological pathways are also known to exhibit mutual interactions (eg, inflammation with thrombosis/coagulation and with autonomic function). The pathways are also likely to be principally active at differing time points (eg, more rapid cardiovascular effects of autonomic imbalance than systemic inflammation) and likely vary in importance in relation to different durations of exposure and in causing different cardiovascular sequelae. The chemical characteristics and sizes of inhaled PM may also determine the pathways activated. As opposed to UFPs or some particulate components or chemicals, larger fine and coarse PM are not likely transported into the circulation to any large degree and therefore are more apt to require intermediary pathways to cause extrapulmonary effects. It may also be that surface-bound components may be delivered into the circulation, whereas larger particles themselves serve as a means to deliver the responsible constituent into the pulmonary tree.

The hyperacute physiological responses that occur minutes to hours after PM inhalation are likely mediated principally via pathways 2 and 3. These include ANS-mediated changes (eg, elevated BP, arrhythmias, and vasoconstriction), along with direct effects of circulating PM constituents on platelets (eg, procoagulant and thrombotic changes) and the endothelium (eg, oxidative stress and vasoconstriction). These responses are liable to be the dominant mechanisms responsible for the actual triggering of acute cardiovascular events. Clinically meaningful effects undoubtedly become manifest only in the context of a susceptible patient, typified by the individual with "vulnerable plaque" in the case of acute coronary syndromes or strokes, "vulnerable myocardium" in the context of arrhythmias, or the "vulnerable circulation" in the context of a heart failure patient at risk for circulatory overload. On the other hand, the biological consequences of systemic inflammation, such as activated white cells and elevated cytokines (via pathway 1), typically require longer periods. Their penultimate effect is the induction of a chronic underlying vulnerable milieu that leads to atherosclerotic plaque vulnerability, enhanced coagulation/thrombotic and arrhythmia potential, and impaired basal vasomotor balance. These actions thereby predispose individuals for future cardiovascular events, particularly when they occur in conjunction with traditional risk factors or prompt susceptibility to the acute biological actions (via pathways 2 and 3) of later air pollution exposures.

This hypothetical segregation of the biological effects of PM exposure as acute or chronic and into the broad pathways is artificial. It is useful in the broad context of understanding potential pathways; however, there is no doubt a large degree of overlap among the mechanisms and the timing of physiological responses. This is most aptly conveyed as the influence of "acute on chronic" actions of exposure. For example, the activation of circulating platelets by the pulmonary deposition of particles or lung inflammation (eg, by P-selectin–dependent pathways, histamine, or IL-6) could occur within hours and more rapidly than typical of the other consequences of inflammation (eg, progression of atherosclerosis). In the presence of a vulnerable or eroded coronary plaque due to long-term air pollution exposure, this sudden prothrombotic tendency could instigate an acute ischemic event (alone or in conjunction with other effects of short-term PM exposure via pathways 2 and 3). Furthermore, the epidemiological cohort studies demonstrate a larger relative risk for increased cardiovascular-related mortality than for morbidity.[72,73,227,274] If this is a true biological response and not simply a statistical phenomenon or a shortcoming of the available data, it not only suggests that exposures are capable of triggering acute cardiovascular events but that PM air pollution may also exaggerate their severity even if they would have otherwise occurred for reasons unrelated to air pollution. Therefore, exposure to PM could also be responsible for promoting fatal over nonfatal events.

Conclusions and Recommendations

A wide array of new studies that range from epidemiology to molecular and toxicological experiments have provided additional persuasive evidence that present-day levels of air pollutants contribute to cardiovascular morbidity and mortality. Although not unexpected given the numerous and heterogeneous nature of the published studies, all findings related to every single cardiovascular end point have not been consistent. However, the overall weight of scientific evidence now supports several new conclusions since the 2004 statement. These consensus points are given below by the AHA writing group after considering the strength, consistency, and coherence of the epidemiological findings, as well as in the context of evaluating the extent of the studies that provided related mechanistic support.

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

- The preponderance of findings indicate that short-term exposure to $PM_{2.5}$ over a period of a few hours to weeks can trigger CVD-related mortality and nonfatal events, including myocardial ischemia and MIs, heart failure, arrhythmias, and strokes.
- The increase in risk for acute $PM_{2.5}$-associated cardiovascular morbidity and mortality is principally among susceptible, but not necessarily critically ill, individuals. Several studies suggest that susceptible individuals at greater risk may include the elderly, patients with preexisting coronary artery disease, and perhaps those with diabetes. Recent data suggest that women and obese individuals might also be at higher risk.
- Most studies support the idea that longer-term $PM_{2.5}$ exposures increase the risk for cardiovascular mortality to an even greater extent than short-term exposures. Because most studies have focused on mortality data, the effect of long-term exposures on nonfatal cardiovascular events is less consistent and requires more investigation.
- The $PM_{2.5}$ concentration–cardiovascular risk relationships for both short- and long-term exposures appear to be monotonic, extending below 15 $\mu g/m^3$ (the 2006 annual NAAQS level) without a discernable "safe" threshold.
- Long-term exposure to elevated concentrations of ambient $PM_{2.5}$ at levels encountered in the present-day environment (ie, any increase by 10 $\mu g/m^3$) reduces life expectancy within a population probably by several months to a few years. Given that $PM_{2.5}$ is most strongly associated with cardiovascular deaths in the cohort studies, the reduced life expectancy is most likely predominantly due to excess cardiovascular mortality.
- The available studies are suggestive that reductions in PM levels decrease cardiovascular mortality within a time frame as short as a few years.
- Many potential biological mechanisms exist whereby PM exposure could exacerbate existing CVDs and trigger acute cardiovascular events (over the short term) and instigate or accelerate chronic CVDs (over the long run). Experimental support is increasingly strong for several mechanisms, which lends biological plausibility for the epidemiological findings.
- The existing evidence suggests that PM air pollution is capable of augmenting the development and progression of atherosclerosis. There is some support for a potential effect on several other chronic CVDs, including hypertension, heart failure, and diabetes.
- Most recent studies support the conclusion that the overall absolute risk for mortality due to PM exposure is greater for cardiovascular than pulmonary diseases after both short- and long-term exposures.

There are several additional areas worthy of highlighting in which the study results are reasonably consistent but in which the writing group believed further research was required to formulate firm conclusions.

- Although there is only limited epidemiological evidence directly linking UFPs with cardiovascular health problems,[262] the toxicological and experimental exposure evidence is suggestive that this size fraction may pose a particularly high risk to the cardiovascular system. The likelihood of health effects and the causal pathways mediated specifically by UFP exposure have been debated among experts recently.[418] Future research may help to more fully elucidate whether particles within the ultrafine size range (0.001 to 0.1 μm) and/or their constituents are more harmful to the cardiovascular system or pose a relatively greater cardiovascular risk than particles between 0.1 and 2.5 μm in diameter.
- Similarly, many studies have found a strong association between metrics of traffic-related air pollution exposure and elevated cardiovascular risk. Whether this represents the harmful effects of UFPs or diesel exhaust particulates, major components of the traffic mixture, or other pollution components is unclear. Diesel and UFPs possess toxic properties that instigate harmful biological responses in experimental models. However, the particle size fraction(s) and roles played by other copollutants (gases, VOCs, SVOCs) within the traffic-related mixture have not been fully elucidated. Nevertheless, traffic-related pollution as a whole appears to be a specific source associated with cardiovascular risk. It likely poses a major public health burden, regardless of a putative higher toxicity, because of the commonness of exposure in modern society (eg, accounting for ≈60% of daily UFP exposure; http://www.catf.us/projects/diesel/).
- The importance of other specific sources, regional differences in pollution composition, and other specific constituents remains less clear. However, toxicological studies have identified several transition metals (eg, iron, vanadium, nickel, copper, and zinc), organic carbon species, semiquinones, and endotoxin as specific PM-related components capable of prompting oxidative stress and inflammation and thus likely imparting biological harm. Some source-apportionment studies also demonstrate that attention should be given to these compounds as being among the most likely mediators of clinical CVD. More studies are required in this regard to clarify this issue and to better define these and other potentially responsible constituents and sources.
- Although the focus of the present statement is on PM, we recognize that other air pollutants may also pose cardiovascular risk alone or in conjunction with fine-particle exposure. In this context, we believe additional research is necessary to make firm conclusions regarding the independent cardiovascular risks posed by several gaseous pollutants (eg, ozone and NO_2). Although ozone has been linked to increased cardiopulmonary mortality,[50] strokes,[126] and MIs[419] in some short-term studies, long-term exposure was not associated with cardiovascular mortality after accounting for PM in a recent analysis.[87] The recent finding that small changes in low levels of ambient carbon monoxide concentrations are related to cardiovascular hospitalizations also merits further exploration.[420]
- Several secondary aerosols (eg, nitrate and sulfate) are often associated with cardiovascular mortality; however, whether these compounds are directly harmful or are surrogate markers of toxic sources of exposure requires

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

more investigation. Similarly, the current literature regarding the independent cardiovascular risks posed by coarse particles is mixed, with most recent findings not supporting an association after accounting for the effects of $PM_{2.5}$.[43,72,104]

- Several recent cohort studies and intermediate end-point experiments suggest that obese individuals (and/or those with the metabolic syndrome) may be a susceptible population at greater risk for cardiovascular events due to $PM_{2.5}$ exposure. This is a tremendously important public health issue to corroborate because of the enormous and growing prevalence of obesity worldwide.

This updated review by the AHA writing group corroborates and strengthens the conclusions of the initial scientific statement. In this context, we agree with the concept and continue to support measures based on scientific evidence, such as the US EPA NAAQS, that seek to control PM levels to protect the public health. Because the evidence reviewed supports that there is no safe threshold, it appears that public health benefits would accrue from lowering $PM_{2.5}$ concentrations even below present-day annual (15 $\mu g/m^3$) and 24-hour (35 $\mu g/m^3$) NAAQS, if feasible, to optimally protect the most susceptible populations. Evaluations of the effectiveness of such efforts would be warranted as well. Within the framework of attempting to establish causality between associated variables in epidemiological studies, there are several generally accepted "aspects" that have been evaluated (the following phrases in italics per the Bradford Hill criteria)[421]: With regard to cardiovascular mortality and $PM_{2.5}$ exposure, there is a *consistent association* that satisfies both a *temporal and exposure-response relationship*. There is *coherence of findings* among several fields of science, including toxicology, human and animal exposures, and different types of epidemiological studies and time frames of exposure. Rigorous experiments demonstrate multiple *plausible biological mechanisms*. Finally, natural experiments have confirmed that a change (ie, reduction) in exposure produces a change (ie, decrease) in cardiovascular mortality. In this case, *specificity of outcomes* and *strength of the observation* are less pertinent, because PM exposure could be capable of causing multiple different types of events (eg, MIs, arrhythmias, and heart failure exacerbations), and the overall cardiovascular mortality relative risk posed for any single individual is expected to be small. Nevertheless, given the ubiquity of exposure, the overall public health consequences can be substantial and observable in population- or large cohort–based studies.

It is the opinion of the writing group that the overall evidence is consistent with a causal relationship between $PM_{2.5}$ exposure and cardiovascular morbidity and mortality. This body of evidence has grown and has been strengthened substantially since publication of the first AHA scientific statement.[1] At present, no credible alternative explanation exists. These conclusions of our independent review are broadly similar to those found in the EPA's Integrated Science Assessment for Particulate Matter final report (http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=216546). In summary, the AHA writing group deems that $PM_{2.5}$ exposure is a "modifiable factor contributing to cardiovascular morbidity and mortality."

Clinical Recommendations

Several precautionary recommendations can be made for healthcare providers who interact with individuals who are at risk for CVDs. Although they have not been clinically tested or proven to reduce mortality, they are practical and feasible measures that may help to reduce exposures to air pollution and therefore potentially lower the associated cardiovascular risk. Moreover, a recent observational study found that patient awareness of air quality indices and media alerts along with health professional advice can significantly affect reported changes in outdoor activity to avoid exposure to air pollution.[422]

- Evidence-based appropriate treatment of the traditional cardiovascular risk factors should be emphasized. This may also lessen the susceptibility of patients to air pollution exposures.
- All patients with CVD should be educated about the cardiovascular risks posed by air pollution.
- Consideration should also be given to educating patients without CVD but who are at high risk (eg, the elderly, individuals with the metabolic syndrome or multiple risk factors, and those with diabetes).
- Part of patient education should include the provision of information regarding the available sources (local and national newspapers [*USA Today*], EPA World Wide Web site [http://airnow.gov/], and The Weather Channel and its World Wide Web site [http://www.weather.com/]) that provide a daily EPA Air Quality Index.
- On the basis of the forecast Air Quality Index, prudent recommendations for reducing exposure and limiting activity should be provided based on the patient's level of risk. A list of such recommendations is provided on the EPA World Wide Web site (http://airnow.gov/). For example, when the Air Quality Index for PM is "unhealthy" (151 to 200), then the recommendations are as follows: "People with heart or lung disease, older adults, and children should avoid prolonged or heavy exertion. Everyone else should reduce prolonged or heavy exertion." The action recommendations are as follows: "You can reduce your exposure to particles by 1) planning strenuous activity when particle levels are forecast to be lower, 2) reducing the amount of time spent at vigorous activity, or 3) choosing a less strenuous activity (eg, going for a walk instead of a jog). When particle levels are high outdoors, they also can be high indoors. Certain filters and room air cleaners are available that can help reduce particles indoors."
- Practical recommendations to reduce air pollution exposure should be given to at-risk patients. Although unproven to reduce cardiovascular events, there are a number of prudent and feasible measures, including reducing optional or unnecessary exposures. Additional measures could include eliminating or reducing nonmandatory travel to highly polluted regions and avoiding exposures or outdoor activities (eg, exercising, commut-

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

ing) during highly polluted times (eg, rush hours) or in proximity to major sources of pollution (eg, roadways, industrial sources). Choosing to exercise indoors with windows closed and using efficient air conditioning and filtering systems may be prudent for certain high-risk patients, particularly during peak pollution periods. Indeed, not only can central air conditioners reduce the indoor exposure level to PM from outdoor sources, there is some evidence that they might reduce the risk for cardiovascular hospitalizations associated with higher ambient pollution levels.[423] If travel/commutes cannot be avoided, maintaining optimal car filter systems, driving with windows closed, and recycling inside vehicle air may help reduce PM exposures (http://www.catf.us/projects/diesel/).[424,425]

However, at present, no specific recommendations regarding the appropriateness of undertaking more aggressive measures, even those shown to provide some benefits in a few studies (eg, wearing facemasks, installing PM filters in households), can be made based on the limited evidence. Similarly, although measures that decrease long-term PM exposures may produce even greater cardiovascular health benefits than the provided recommendations that focus on reducing short-term exposures, no specific recommendations (eg, moving to less polluted regions) can be prudently made at this time given the limited evidence. We acknowledge that occupational and indoor sources along with secondhand tobacco smoke are additional significant sources of personal PM exposures that should be avoided or reduced as much as possible. Finally, in developing nations, reducing exposure to indoor cooking sources of PM and air pollution from biomass combustion is a major issue of concern.[426] Additional suggestions are available on the EPA World Wide Web site.

Finally, although the existing evidence supports a causal relationship between $PM_{2.5}$ and cardiovascular mortality, we acknowledge the importance of continued research in areas of controversy and uncertainty to further understand the full nature of this issue. Although numerous insights have greatly enhanced our understanding of the PM-cardiovascular relationship since the first AHA statement was published,[1] the following list represents broad strategic avenues for future investigation:

Mechanistic Studies

- Better describe the physiological relevance in humans and the fundamental details of the mechanisms underlying the intermediate general mediating pathways (ie, PM or constituent transport into the circulation versus effects of inflammatory cytokines or activated immune cells versus ANS imbalance or other pathways) through which PM inhalation might mediate cardiovascular effects remote from the site of pulmonary deposition.
- Understand the clinical significance and relative importance of the observed biological responses (eg, vascular dysfunction, thrombosis, arrhythmia, ANS imbalance) in relation to the various causes of PM-mediated cardiovascular morbidity and mortality.
- Examine the efficacy of preventive measures (eg, patient education) and treatment modalities (eg, statins, antioxidants, fish oil, treatment of traditional risk factors, and reducing exposures by engineering controls, including filtration, personal protection via facemasks, or behavior modification) on cardiovascular health outcomes.
- Investigate the interaction between preexisting traditional cardiovascular risk factors (eg, diabetes, hypertension) and PM exposure, as well as the potential of air pollutants to exacerbate or worsen these risk factors. Determine the extent to which treatment of such factors (eg, with statins, aspirin, or angiotensin-converting enzyme inhibitors), especially among patients with known CVD, may modify the risk associated with PM exposure.
- Describe the biological effects of acute on top of chronic exposures (eg, synergistic effects versus reduced susceptibility to acute exposures due to augmented protective mechanisms).
- Determine the ability of long-term exposure to precipitate the development of chronic diseases, including clinically relevant atherosclerosis, hypertension, diabetes, and other vascular, metabolic, renal, or neurological diseases.

Epidemiological and Exposure Studies

- Expand our knowledge related to the "responsible" PM pollution constituents (eg, metals, organic compounds, semiquinones, endotoxin, and VOC and SVOC compounds), size fractions (eg, UFPs), sources (eg, traffic, power generation, and biomass combustion), and mixtures of pollutants.
- Investigate the cardiovascular health implications and importance of regional and intracity differences in composition and combinations of pollutants.
- Better understand the effects of mixtures of ambient pollutants (ie, potential synergism between PM and gaseous or vapor-phase pollutants such as ozone).
- Investigate the feasibility and utility of quantifying risk coefficients (concentration-response functions) according to PM source or relevant indices of pollutant mixtures, as a function of susceptibility (eg, age, preexisting disease), for reliable application in integrated, multipollutant risk assessments.
- Investigate the relative importance of various time frames of exposure in relation to PM causing cardiovascular events, including the relevance of epochs not well described, such as ultra-acute peak PM excursions (eg, 1 to 2 hours) and exposures of intermediate duration (eg, 1 to 12 months).
- Better document the time course and specific cardiovascular health benefits induced by reductions in PM.
- Better define susceptible individuals or vulnerable populations.
- Determine whether any "safe" PM threshold concentration exists that eliminates both acute and chronic cardiovascular effects in healthy and susceptible individuals and at a population level.

Acknowledgments

We would like to thank Robert Bard Consulting for reviewing and editing the manuscript and Tom Dann from Environment Canada and Joseph Pinto from the US EPA for assistance in the preparation of Table 1.

Roadway Proximity and Risk of Sudden Cardiac Death in Women

Jaime E. Hart, ScD; Stephanie E. Chiuve, ScD; Francine Laden, ScD; Christine M. Albert, MD

Background—Sudden cardiac death (SCD) is a major source of mortality and is the first manifestation of heart disease for the majority of cases. Thus, there is a definite need to identify risk factors for SCD that can be modified at the population level. Exposure to traffic, measured by residential roadway proximity, has been shown to be associated with an increased risk of cardiovascular disease. Our objective was to determine whether roadway proximity was associated with an increased risk of SCD and to compare that risk with the risk of other coronary heart disease outcomes.

Methods and Results—A total of 523 cases of SCD were identified over 26 years of follow-up among 107 130 members of the prospective Nurses' Health Study. We calculated residential distance to roadways at all residential addresses from 1986 to 2012. In age- and race-adjusted models, women living within 50 m of a major roadway had an elevated risk of SCD (hazard ratio=1.56; 95% confidence interval, 1.18–2.05). The association was attenuated but still statistically significant after controlling for potential confounders and mediators (hazard ratio=1.38; 95% confidence interval, 1.04–1.82). The equivalent adjusted hazard ratios for nonfatal myocardial infarction and fatal coronary heart disease were 1.08 (95% confidence interval, 0.96–1.23) and 1.24 (95% confidence interval, 1.03–1.50), respectively.

Conclusions—Among this sample of middle-aged and older women, roadway proximity was associated with elevated and statistically significant risks of SCD and fatal coronary heart disease, even after controlling for other cardiovascular risk factors. **(*Circulation*. 2014;130:1474-1482.)**

Key Words: air pollutants ■ air pollution ■ coronary disease ■ death, sudden

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

Sudden cardiac death (SCD) accounts for ≈180 000 to 400 000 deaths in the United States each year.[1] SCD is responsible for more than half of the cardiovascular deaths and 15% to 20% of total deaths each year and is the first manifestation of heart disease for a large proportion of victims,[2] especially women.[3] Therefore, there is a need to identify risk factors that can be modified on a population level to broadly affect SCD risk.

Clinical Perspective on p 1482

Long-term exposures associated with traffic such as air pollution and noise have been associated with increased mortality from coronary heart disease (CHD),[4–7] and associations with fatal CHD have typically been stronger than for nonfatal events.[8,9] Short-term exposure to air pollution or traffic has also been associated with ventricular arrhythmias in patients with implantable cardioverter-defibrillators[10] and with elevations in the risk of out-of-hospital cardiac arrest in most but not all studies.[11–19] Therefore, long-term exposure to traffic may be associated with SCD, both through the development of underlying atherosclerosis and by influencing myocardial vulnerability to lethal ventricular arrhythmias.[20]

Previous studies, including our own, have observed modest elevations in incident CHD (combined nonfatal and fatal) among individuals who live closer to major roadways;[21–24] but the impact of this exposure on SCD risk is unknown. Our present objective was to determine whether exposure to traffic, measured by roadway proximity, leads to an increased risk of SCD in women, in whom CHD has been demonstrated to underlie a lower percentage of SCDs than in men.[25,26] We also sought to compare risk estimates for SCD with those for nonfatal and fatal CHD outcomes in this cohort.

Methods

Study Population

The Nurses' Health Study (NHS) is a prospective cohort study that began in 1976 with 121 701 married female registered nurses, 30 to 55 years old, who completed a mailed questionnaire and provided implied informed consent. At the study inception, the nurses resided in 11 states (California, Connecticut, Florida, Massachusetts,

Maryland, Michigan, New Jersey, New York, Ohio, Pennsylvania, and Texas); however, because of residential mobility, there is now at least 1 cohort member in all 50 states. Follow-up questionnaires, with response rates >90%, are mailed every 2 years to update information on risk factors and the occurrence of major illnesses. These questionnaires also provide updated information on residential address. Women were included in the present study if they were still responding to questionnaires and had at least 1 home address in 1986 to 2012 that was geocoded to the street-segment level (so that roadway proximity could be calculated). Women were excluded if they had cancer (other than nonmelanoma skin cancer) or cardiovascular disease or had died before baseline. The study protocol was approved by the Institutional Review Board of Brigham and Women's Hospital.

Outcome Assessment

On all questionnaires, we inquire about the occurrence of physician-diagnosed CHD events, and deaths are identified by reports from next-of-kin or postal authorities or by searches of the National Death Index. Details on the method of classifying SCD in this cohort have been published previously.[3] Briefly, SCDs were confirmed by physician review of medical records and next-of-kin reports on the circumstances surrounding the death if not adequately documented in the medical record. Cardiac deaths were considered sudden if the death or cardiac arrest occurred within 1 hour of the onset of symptoms. To increase specificity for arrhythmic death, we also required that there be no evidence of circulatory collapse or a neurological event before the disappearance of the pulse.[27] Unwitnessed deaths or deaths that occurred during sleep in which the participant was documented to be symptom free within the preceding 24 hours were considered probable SCDs if an autopsy or circumstances suggested that the death could have been arrhythmic.[28]

Cases of definite fatal CHD (*International Classification of Disease, Eighth and Ninth Revision* codes 410–412:, *International Classification of Disease, 10th Revision* codes I21–I22) were confirmed by hospital records or autopsy or if CHD was listed as the underlying and most plausible cause of death on the death certificate and there was prior evidence of CHD. Probable fatal CHD events include deaths for which medical records surrounding the death were not available but CHD was the underlying cause on the death certificate or a search of the National Death Index or a family member provided supporting information. Given the relatively low prevalence of CHD in female sudden cardiac death and arrest victims,[25,26,29,30] SCD cases not fulfilling the above definition or cases in which another primary underlying cause of death was identified by history or autopsy were not included as fatal CHD events.

Nonfatal myocardial infarction (MI) was classified as definite if the World Health Organization criteria were met, specifically symptoms and either ECG-detected changes or elevated cardiac enzyme concentrations. Cases of nonfatal MIs were designated as probable if an interview or letter confirming hospitalization was obtained and medical records were unavailable.

Roadway Proximity

We calculated roadway proximity at each mailing address from 1986 on as a proxy for traffic exposure. Distance (in meters) was determined with the Geographical Information System software (ArcGIS 10.2, ESRI, Redlands, CA). ESRI StreetMap Pro 2007 road segments were selected to include the 3 largest US Census Feature Class Codes: A1, primary roads, typically interstate highways, with limited access, division between the opposing directions of traffic, and defined exits; A2, primary major, noninterstate highways and major roads without access restrictions; or A3, smaller, secondary roads, usually with >2 lanes). On the basis of the distributions in the cohort and exposure studies showing exponential decays in exposures with decreasing roadway proximity,[31] we created distance categories of 0 to 49, 50 to 199, 200 to 499, and ≥500 m. In sensitivity analyses, we also examined continuous measures and other cut points to determine the robustness of results to our a priori choices.

Potential Confounders

Information on potential confounders is available every 2 years (4 years for diet) from the follow-up questionnaires and can be used to assign updated covariate values. We included a number of risk factors for SCD and/or CHD as possible confounders: age (in months), race (white, black, other, or multiple races), calendar year, physical activity (hours per week), body mass index (kilograms per meter squared), alcohol consumption (grams per day), menopausal status (premenopausal, postmenopausal, or unknown/dubious), and hormone use (never, current, or former), family history of MI (none, at age <60 years, or at age ≥60 years), and incidence of diabetes mellitus or cancer. We used lifetime smoking history to calculate pack-years and to determine smoking status (current, former, or never). Diet was assessed by calculating a score using the 2010 Alternate Healthy Eating Index.[32] This score includes a number of components including higher intakes of vegetables, fruit, nuts, soy and cereal fiber, moderate alcohol consumption, low intake of red and processed meats, high ratios of polyunsaturated to saturated fat; low intake of *trans* fat; and multivitamin use of ≥5 years We also adjusted for aspirin, vitamin E, and multivitamin use. Information on secondhand smoke exposure (during childhood, at home, and at work) was collected on the 1982 questionnaire. To control for regional differences in traffic and disease risk, we controlled for Census region (Northeast, Midwest, West, and South). To control for area-level socioeconomic status, we included Census tract–level median income and house value. In sensitivity analyses, we additionally adjusted for incident comorbidities that may be mediators of the association between traffic exposure and SCD (high blood pressure, hypercholesterolemia, stroke, or CHD) or CHD (high blood pressure, hypercholesterolemia, or stroke).

Statistical Methods

Separate analyses were performed for each outcome. Person-months of follow-up time were calculated from June 1986 until the end of available follow-up (December 2012 for SCD, May 2010 for nonfatal MI and fatal CHD), death, or loss to follow-up. We did not censor person-time at the incidence of nonfatal MI for the fatal outcomes. Time-varying Cox proportional hazards models were used to assess the relationship of each outcome with roadway proximity. Hazard ratios (HRs) and 95% confidence intervals (CIs) were calculated for each category of roadway proximity compared with the farthest category (≥500 m). We examined the linearity of the continuous associations 0 to 499 m (compared with ≥500 m) using cubic splines.[33] The data set was converted to an Anderson-Gill data structure with a record for each 2-year time period, including person-time, the exposure during that time period, whether the person was censored during the interval, and covariate information. All models were based on a biennial time scale and were stratified by age in months and time period. The proportional hazard assumption was verified for all analyses by including interaction terms for age and time period and performing a likelihood ratio test comparing models with and without the interaction terms. The percent of the roadway proximity–outcome association explained by the potential mediators was calculated as follows: $[(HR_{\text{multivariable model}} - HR_{\text{multivariable and mediator model}})/(HR_{\text{multivariable model}} - 1)] \times 100\%$.[34] In sensitivity analyses, we considered models restricted to definite cases of each outcome to determine the impact of stricter case definitions on our conclusions. To examine possible effect modification by race (white versus other) and smoking status (never versus ever and current versus former/never), we calculated stratum-specific effect estimates and examined the statistical significance of effect modification using likelihood ratio tests. Using publically available software,[35] we also estimated the population-attributable risk associated with living <500 m from A1 to A3 roadways. An α level of 0.05 was used to determine statistical significance.

Results

Characteristics of the study sample (n=107 130) over the full period of follow-up are presented in Table 1 for the whole cohort and by roadway proximity category. The women were

Values are mean (SD) when appropriate and, except for age, are standardized to the age distribution of the study population. Note that participants may be in multiple exposure categories during the study follow-up. MI indicates myocardial infarction; and NHS, Nurses' Health Study.

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

64.3 years old on average with an average body mass index of 26.3 kg/m^2 and were mostly white (94%), postmenopausal (86%), and never (44%) or former (42%) smokers. Most (58%) exercised <2 h/wk. Overall, there was little difference in these characteristics across the different categories of roadway proximity except for region; women in the Northeast tended to live closer to roadways than women in other regions.

Roadway Proximity and SCD

During the 26 years of follow-up, a total of 523 cases (328 definite, 195 probable) of SCD were observed. The associations of roadway proximity with SCD are presented in Table 2. In basic models adjusted for age, race, and calendar time, women living within 50 m of a roadway had a higher risk of SCD (HR, 1.56; 95% CI, 1.18–2.05) compared with women living farther away (≥500 m). The dose-response relationship between roadway proximity and SCD risk was linear as determined by cubic splines, and each 100 m closer to roadways was associated with an 8% increased risk for SCD (95% CI, 3–14). In multivariable models controlling for potential confounders, HRs were attenuated but remained statistically significant in both the categorical (HR, 1.40; 95% CI, 1.06–1.85 for <50 versus 500 m) and continuous (HR, 1.06; 95% CI, 1.01–1.12 per 100 m) analyses. Additional adjustment for incident comorbidities, including incident CHD, potentially on the causal pathway had little effect on the HRs (4.3% mediation). In sensitivity analyses excluding probable SCDs or nonwhites, the magnitude of the associations was similar (multivariable HR, 1.33, 95% CI, 0.94–1.89; and multivariable HR, 1.32, 95% CI, 0.99–1.76 for <50 versus 500 m). These associations also did not significantly differ by region of residence, race, or smoking status; however, the HR associated with living <50 versus 500 m from a roadway was higher among ever smokers (HR, 1.56; 95% CI, 1.08–2.23) compared with nonsmokers (HR, 1.22; 95% CI, 0.80–1.97; Table I in the online-only Data Supplement).

Roadway Proximity and Nonfatal MI and Fatal CHD

During 24 years of follow-up, 2731 cases (1813 definite, 918 probable) of nonfatal MI and 1159 cases (794 definite, 365 probable) of fatal CHD were identified. The associations with roadway proximity and each outcome are shown in Table 3. In multivariable models, the risk of fatal CHD (HR, 1.24; 95% CI, 1.03–1.49) was statistically significantly higher among women living within 50 m of an A1 to A3 road compared with women living ≥500 m away, and the HR for each additional 100 m closer in proximity was 1.04 (95% CI, 1.00–1.07). This association was slightly attenuated when fatal CHD events also considered SCDs (n=152) were excluded from the end point (multivariable HR, 1.21, 95% CI, 0.99–1.48 for <50 versus 500 m; and multivariable HR, 1.03, 95% CI, 0.99–1.07

per 100 m). Risks of nonfatal MI were more modest in magnitude and were not statistically significant in multivariable models. Similar to our results for SCD, results for fatal CHD and nonfatal MI were essentially unchanged when additionally adjusted for incidence of other comorbidities that might be in the causal pathway (0.1% and 0.2% mediation for nonfatal MI and fatal CHD, respectively), when other categorical cut points were considered, and in models excluding probable events or nonwhites (data not shown). There was also no evidence of effect modification by race or region of residence (data not shown) or smoking status (Table II in the online-only Data Supplement).

Population-Attributable Risks

Over the course of the study, 75% of the total person-years observed were spent at residences within 499 m of an A1 to A3 roadway. The multivariable adjusted HRs for the categorical variable (0–49, 50–199, and 200–499 versus ≥500 m) translate into population-attributable risks of 17.9% (95% CI, 0.1–34.7), 11.6% (95% CI, −1.1 to 23.9), and 6.8% (95% CI, −1.4 to 14.9) for SCD, fatal CHD, and nonfatal MI, respectively, in this sample of women.

Discussion

Among this sample of middle-aged and older women, roadway proximity was associated with an elevation in the risk of SCD. Even after adjustment for potential confounders and mediators, women who lived within 50 m of a major roadway had a 38% higher hazard (95% CI, 1.04–1.82) of experiencing SCD compared with women living ≥500 m away. The association was linear, and each 100 m closer to a major roadway was associated with a 6% elevation in

§Linear models for distances 0 to 499 m compared with addresses ≥500 m away.

the HR (95% CI, 1–11). Proximity to a major roadway was also statistically significantly associated with fatal CHD but to a lesser magnitude. These results suggest that traffic exposure, as measured by roadway proximity, may increase the risk of death resulting from CHD and may increase the propensity for fatal ventricular arrhythmias. If the observed relationships are causal, these results suggest that roadway exposures may underlie 17.9%, 11.6%, and 6.8% of SCDs, fatal CHDs, and nonfatal MIs, respectively, in this population. For the end point of SCD, these population-attributable risks are comparable to or greater than the contributions made by smoking, diet, and obesity in this population.[36]

To the best of our knowledge, this is the first study to examine the impact of residential roadway proximity on the risk of SCD. However, a few case-crossover studies have examined the impact of short-term traffic-related air pollution exposures (most often fine particulate matter [$PM_{2.5}$], carbon monoxide, or oxides of nitrogen), and risk of out-of-hospital cardiac arrests. As summarized in a recent review,[37] the majority have used administrative databases to identify cases and local air pollution monitoring networks to assign pollution measures for a variety of pollutants on the day of the event and a varying number of previous days. In studies based in Rome, Italy,[13] Melbourne, Australia,[11] Helsinki, Finland,[16] Stockholm, Sweden,[38] Indianapolis, IN,[15] New York, NY,[17] and Houston, TX,[12] elevated risks were observed with increased levels of particulate matter or other pollutants on the day of or up to 3 days preceding the cardiac arrest. However, in studies from Washington State[14,18] and Copenhagen, Denmark,[19] consistent associations were not found between levels of particulate matter measured in the days before out-of-hospital cardiac arrest compared with control days from the same month. Although it is not possible to directly compare these studies with ours, the preponderance of evidence suggests that short-term exposures to traffic-related pollutants are associated with acute increases in risk of out-of-hospital cardiac arrests.

In terms of mechanisms underlying these associations, there is a growing body of literature supporting an association between short-term (hourly, daily) exposures to air pollution, especially those from traffic sources, and ventricular arrhythmias.[10] The majority of these studies have been conducted in selected high-risk populations of patients with implanted cardiac defibrillators in whom the events can be identified with fine temporal resolution. In the first such study, based in the Boston, MA, area, recent exposures to NO_2 were associated with an increased risk of arrhythmias, and multiple events were associated with a number of other traffic-related exposures.[39] A second study in the same geographic area observed a positive linear association between $PM_{2.5}$ and the risk of arrhythmias.[40] Similar findings with different measures of air pollution have been observed in studies from St. Louis, MO, Gothenburg, Germany, and Stockholm, Sweden, but not in studies of patients in Vancouver, BC, Canada, and Atlanta, GA.[10] Because fatal ventricular arrhythmias underlie a large proportion of SCD and thus contribute to fatal CHD deaths, these data provide a potential biological mechanism underlying at least part of our observed association between traffic-related exposures and SCD and fatal CHD.

Our data suggest that there may also be a more general association between roadway proximity and fatal CHD events that may not be entirely explained by effects on SCD. Short-term exposure to traffic has been associated with transiently increased risks of nonfatal MI,[41] and long-term exposure to traffic or roadways has been associated with higher risks of fatal and nonfatal CHD events.[21–23] In the Atherosclerosis Risk in Communities (ARIC) study, living within 300 m of a major road was associated with a 12% increased risk of CHD in a population of ≈13 000 middle-aged men and women, with stronger risks for those living near roads with higher traffic density.[21] In a case-control study in Massachusetts, each interquartile-range increase in traffic density was associated with a 4% (95% CI, 2–7) increased risk of acute MI.[23] Our previous analyses in the NHS found that women living at residences consistently close to traffic over follow-up were at a higher risk for incident total CHD (HR, 1.11; 95% CI, 1.01–1.21) than women who live consistently at addresses farther away.[22] Although these studies did not specifically compare associations for fatal and nonfatal events, other studies from Stockholm and Rome examining long-term exposures to traffic-related air pollution have demonstrated stronger associations with fatal MI end points and out-of-hospital deaths compared with nonfatal events,[42,43] consistent with our results.

It is important to note that although there was minimal overlap between SCD and fatal CHD events, some degree of undetected overlap between SCD and fatal CHD events undoubtedly exists and is unavoidable in this epidemiological study. In prior studies,[25,26,29] CHD is detected at autopsy or on extensive clinical evaluation in slightly fewer than half of women who suffer a sudden cardiac arrest/SCD.[25,26,29,30] In our study, only 30% of SCDs were found to have evidence for CHD before or at the time of death; thus, it is probable that undetected CHD underlies a proportion of the remaining SCDs. Therefore, despite controlling for known CHD in our models, residual confounding by undetected CHD could account for part of the association with SCD. Conversely, the strict but standard[28] definition of SCD used in our study relies on the patient having been observed within the 24 hours before death, and it is probable that some of the fatal CHD events that occurred suddenly may not have been characterized as SCD, either because the deaths were unwitnessed for >24 hours or because details on the circumstances of the death were not available. Therefore, undetected SCDs may underlie some of the residual association between roadway proximity and fatal CHD.

A number of potential biological mechanisms are associated with residential proximity to roadways that could predispose patients to both SCD and fatal CHD apart from acute triggering of ventricular arrhythmias.[44] The primary comorbidities we examined as mediators (high cholesterol and high blood pressure) had little effect on our observed associations, as determined by the percent mediation, suggesting that the effects of roadway proximity on SCD and fatal CHD may be working through other mechanisms. Traffic-related air pollution has also been associated with

Downloaded from http://circ.ahajournals.org/ by guest on October 25, 2017

elevations in systemic inflammation, oxidative stress, heart failure, and alterations in autonomic function and heart rate variability.[44] Residential proximity to major roadways has been directly associated with higher left ventricular mass index[45] and severity of atherosclerosis as measured by coronary calcification.[46] Additionally, traffic noise has been linked to a number of these underlying mechanisms, including heart rate, cardiac output, and oxidative stress, suggesting that traffic exposures may act on cardiovascular disease through a number of underlying biological mechanisms.[47]

This study has several limitations. Our measure of exposure, roadway proximity, is a poor proxy for true traffic exposures such as noise or pollution levels, and it does not provide us with information on temporal changes in exposures that may be associated with triggering of events. These limitations are expected to lead to nondifferential misclassifications of exposure, which would bias our results toward the null. It does have the advantage, however, of allowing us to assess the combined impact of all aspects of near-roadway exposure simultaneously. Additionally, only 15% of the person-time in the cohort was spent at addresses within 50 m of an A1 to A3 roadway, limiting our ability to detect statistically significant effects at the highest exposure levels. Our assumption of similar exposures from all roadways within a given roadway classification is another limitation of our study because time-varying information on traffic volume during our follow-up period is not widely available for the entire contiguous United States for the study period. We also lack information on the temporal and seasonal trends in traffic. This inability to differentiate roads and time periods with higher exposure levels likely leads to nondifferential exposure errors, which would lessen our ability to detect statistically significant effects. Similarly, we do not have information on the amount of time each participant spends at her home or on characteristics of each home such as age, ventilation rate, soundproofing, and orientation relative to prevailing winds and to the roadways. All of these factors would also lead to exposure misclassification and likely partially explain our wide CIs.

As with any observational study, exposures and comorbidities may be incompletely or imperfectly measured, resulting in residual confounding or an inability to adequately detect effect mediation by comorbidities. However, validation studies have suggested that the nurses accurately report many of the CHD risk factors and comorbidity risk factors examined in this study.[48] We also do not have information on medication use just before death (such as QT-prolonging agents), which may mediate our observed associations with SCD. Finally, although women in this cohort live in all portions of the contiguous United States and we did not observe evidence for effect modification by race, the latter analyses were limited by small numbers of nonwhite participants. The participants are also mostly middle-aged to elderly and of middle- to upper-class socioeconomic status. Therefore, it is possible that the results in this population are not generalizable to other races or populations with differing levels of susceptibility to the effects of roadway proximity or differing patterns of exposure.

This large prospective study also has major strengths. Information on residential address and roadway proximity over a 26-year period was available, allowing us to look at the long-term effects of roadway proximity on the risk of SCD over a long time scale, as opposed to the daily or weekly exposures commonly examined. Additionally, the large number of well-validated cases of SCD, nonfatal MI, and fatal CHD allowed us to look at relatively fine-scale changes in exposure with tight control for a number of time-varying risk factors. This wealth of outcome data also provided us with an opportunity to compare the impacts of traffic exposure for a number of outcomes. Finally, the availability of a host of time-varying data on other potential risk factors for our outcomes allowed us to examine the impacts of roadway proximity independently of diet, personal characteristics, socioeconomic status, and other comorbidities.

Conclusions

Living near a major roadway was associated with a significant increase in SCD risk in this sample of US middle-aged women. Although the risk elevations are modest, given the ubiquitous nature of the exposure, the population-attributable risk is significant and comparable to that observed for other major SCD risk factors.[36] In the United States, the US Environmental Protection Agency estimated that 35 million people lived within 300 feet of a major road in 2009,[49] and a growing number of individuals live in close proximity to major roads worldwide. Therefore, exposures related to traffic such as air pollution and noise are widely prevalent and potentially modifiable population-level risk factors for SCD. Because the majority of SCDs occur in individuals considered to be at low risk within the general population, modification of population-level exposures that elevate SCD risk represents an important component of a comprehensive strategy to reduce the burden of SCD in the population.

CLINICAL PERSPECTIVE

Sudden cardiac death (SCD) is a major source of mortality and is the first manifestation of heart disease for the majority of cases. Therefore, modifiable, population-level risk factors for primary prevention are important to identify. Exposure to traffic, measured by residential roadway proximity, is commonly used as a proxy for exposures to air pollution and traffic noise, both of which have been associated with an increased risk of cardiovascular disease, as well as underlying biological mechanisms related to SCD risk. In the present study, we assess the risk of incident SCD, nonfatal myocardial infarction, and fatal coronary heart disease associated with roadway proximity among participants of the Nurses' Health Study, a prospective cohort study. We found that women living closer to large roadways were at an increased risk of SCD and fatal coronary heart disease compared with women living farther away. Although risk elevations are modest, we found that the population-attributable risk for SCD was comparable with that observed for other major SCD risk factors such as smoking, diet, and obesity. These results need to be confirmed in other populations but suggest that exposures to traffic may be an important unidentified risk factor for SCD.

Abstract

Rationale: Few studies have been performed on air pollution effects on lung function in the elderly, a vulnerable population with low reserve capacity, and even fewer have looked at changes in the rate of lung function decline.

Objectives: We evaluated the effect of long-term exposure to black carbon on levels and rates of decline in lung function in the elderly.

Methods: FVC and FEV_1 were measured one to six times during the period 1995–2011 in 858 men participating in the Normative Aging Study. Exposure to black carbon, a tracer of traffic emissions, was estimated by a spatiotemporal land use regression model. We investigated the effects of moving averages of black carbon of 1–5 years before the lung function measurement using linear mixed models.

Measurements and Main Results: A 0.5 $\mu g/m^3$ increase in long-term exposure to black carbon was associated with an additional rate of decline in FVC and FEV_1 of between 0.5% and 0.9% per year, respectively, depending on the averaging time. In addition, black carbon exposure before the baseline visit was associated with lower levels of both FVC and FEV_1, with effect estimates increasing up to 6–7% with a 5-year average exposure.

Conclusions: Our results support adverse effects of long-term exposure to traffic particles on lung function level and rate of decline in the elderly and suggest that functionally significant differences in health and risk of disability occur below the annual Environmental Protection Agency National Air Quality Standards.

Keywords: air pollution; black carbon; FEV_1

Short- and long-term effects of air pollutant exposures on lung function have been studied in children and adults (1–4). Although warranted (5), there are fewer studies in the elderly, a sensitive population, and even fewer looking at changes in the rate of decline in lung function. By 2030, people older than 65 years will represent 19% of the US population (http://www.aoa.gov/aoaroot/aging_statistics/index.aspx). Changes in the lung structure and function during aging alter remodeling phenomenon and respiratory mechanics, which makes the elderly more susceptible to environmental stressors, such as air pollutants. Lung function and accelerated lung function decline are known predictors of mortality

At a Glance Commentary

Scientific Knowledge on the Subject: Although there is compelling evidence that short- and long-term ambient air pollution exposure adversely affect lung function in children and young adults, altered respiratory mechanics in the elderly may put them at increased risk for experiencing toxicologic effects of air pollutants. Few studies have been performed in this increasing and vulnerable population with low reserve capacity, and even fewer have looked at changes in the rate of decline in lung function.

What This Study Adds to the Field: We report robust results indicating lower lung function level and accelerated lung function decline in the elderly after long-term exposure to black carbon. Our findings suggest that levels of particles related to traffic, although within the Environmental Protection Agency annual air quality standards, may contribute to the significant differences in the rate of lung function decline.

risk (6), as is air pollution, especially particles. The mortality risk of particle exposures is greater in the elderly, and is much larger for chronic than for acute exposures. Hence, understanding how long-term air pollution exposure impacts lung function in the elderly is critical in determining whether this is a possible pathway for the mortality and morbidity associated with air pollution.

The use of fixed monitoring to assess exposures to air pollution is being replaced by the use of geocoded exposure to people's residences. These modeled exposures may be based on land use regression (7–9), dispersion models (10), kriging (11), and satellite remote sensing (12, 13). These allow the characterization of exposure contrasts within cities, offer reduced exposure error, and hence provide more precise and less biased estimates. These improvements are particularly important in the elderly, who no longer work and spend most of the time at home.

Adverse effects of short- to medium-term (4–28 days) exposure to black carbon (BC), carbon monoxide, nitrogen dioxide, and particulate matter less than 2.5 μm ($PM_{2.5}$) on FVC and FEV_1 have been reported in the Normative Aging Study (14), a population of elderly subjects followed since the 1960s. BC is a traffic-related particulate pollutant and has been used as a surrogate of exposures to traffic-related particles in general, weighted toward diesel particles. We here examined the effect of long-term averaged BC on long-term levels and rates of decline in lung function in that same cohort.

Methods

More details on the study design, BC exposure, and statistical analysis can be found in the online supplement.

Study Population and Pulmonary Health

Our study included 858 elderly men living in the Boston area, enrolled in the Normative Aging Study cohort (15), who returned for examinations every 3–5 years between 1995 and 2011. During these examinations, height, weight, and medication use (sympathomimetic α and β, anticholinergics) were assessed. Pulmonary disorders confirmed by a physician (asthma, chronic bronchitis, emphysema) and smoking history were collected through the American Thoracic Society questionnaire. FVC and FEV_1 were assessed by spirometric tests performed following the American Thoracic Society guidelines. Methacholine challenge tests were also conducted, as previously reported (14). Participants provided written informed consent and the study was approved by the institutional review boards of all participating institutions.

BC Exposure

We have developed a spatiotemporal land use regression model for traffic particles based on BC in the greater Boston metropolitan area (9). This model for BC has been updated and revised to include data from 148 monitoring stations recording BC levels at some point between October 1995 and August 2011. Daily predictions at the geocoded address of each participant were used to create moving averages of 1–5 years before each examination. Other pollutants were not examined, because we did not have land use regression models for them.

Statistical Analysis

We used separate linear mixed models for each lung function measurement:

$$\begin{aligned}\text{Log}(\text{FVC or } FEV_1)_{it} &= \beta_0 + u_i + \beta_1\ \text{age_baseline}_i + \beta_2\ \Delta\text{age}_{it} \\ &\quad + \beta_3\ \text{black carbon}_{it} + \beta_4\ \text{black carbon}_{it} \\ &\quad \times \Delta\text{age}_{it} + \beta_p Z_{pit} + \varepsilon_{it}, \qquad (1)\end{aligned}$$

where u_i is the random intercept for participant i; age_baseline is the participants age at the time of the first visit; BC is the average BC concentration at the home address of the participants for the preceding 365 days before the visit t, 730 days, and so forth; and Δage is a time trend term expressed in days since the baseline visit. Hence, in this model β_3 measures the cross-sectional effect of BC and β_4 measures the effect of BC on the rate of decline in lung function. Because BC exposures were centered on the mean (i.e., 0.5 $\mu g/m^3$), β_2 is the slope of lung function decline for participants with average exposure. Z represents the *P* covariates controlled for in the model.

All analyses were conducted controlling for a core set of covariates chosen based on biologic knowledge: race, height, weight, education level, smoking status, pack-years, and season. We then examined sensitivity to further control, specifically for asthma, emphysema, chronic bronchitis, methacholine responsiveness, and medication use (level 2); then for coronary heart disease, stroke, hypertension, and diabetes (level 3); and then for BC averaged over the previous week (level 4). We finally tested whether the BC–lung function decline association was stronger in participants older than 65 years versus less than or equal to 65 years, in participants with baseline FEV_1/FVC less than 0.7, and in ever versus never smokers.

Results

Of the 858 men, 24% had one visit, 23% had two visits, 18% had three visits, and 35% had four to six visits. Table 1 shows the characteristics of the participants at the first visit. At the first visit, 75% of the men were older than 68 years. Only 5% of the

*Among current or former smokers.

subjects had less than a high school education, and 70% had at least some college education. Only 5% were active smokers at the time of the first visit, although most of the participants were former smokers.

The 5th to 95th percentile ranges of the long-term BC exposure distribution were 0.9 or 0.8 $\mu g/m^3$ (vs. mean of 0.6), demonstrating the considerable variation in traffic particle exposure across the greater Boston area (Table 2).

Table 3 shows the results of the primary analysis. For each increment of 0.5 $\mu g/m^3$ in long-term BC exposure, we found an additional rate of decline in FVC of between 0.5% and 0.9% per year, depending on the averaging time, and an additional decline of FEV_1 of 0.5% per year, except for the 5-year average, where the decline was 0.8% per year. In addition, BC exposure before the baseline visit was associated with lower baseline levels of both FVC and FEV_1, with effect estimates increasing with averaging time. For the 5-year average before the baseline visit, FEV_1 was 6.7% (95% confidence interval [CI], 9.1–4.4%) lower for each increment of 0.5 $\mu g/m^3$. For FVC, the effect was −5.6% (95% CI, −7.5% to −3.6%). Figure 1 illustrates the expected lung function over time by exposure given this model.

Results were consistent when we further adjusted for asthma, emphysema, chronic bronchitis, methacholine responsiveness, medications, chronic heart disease, stroke, hypertension, and diabetes (Table 4). Spearman correlation between 1-year and 1-week BC exposure was 0.77. When we further adjusted for short-term exposure to BC, the cross-sectional effects of long-term exposure to BC were weaker, but the longitudinal effects were consistent. The effects of BC exposures were the same for participants younger and older than 65 years, and for persons with baseline FEV_1/FVC ratios above and below 0.7. When we compared the effect of BC on the rate of decline in lung function among never versus ever smokers, there was a suggestion of a higher effect on never smokers for FVC and a significant interaction for FEV_1. For a 0.5 $\mu g/m^3$ increase in the 5-year average BC exposure, the increased rate of FEV_1 decline was −1.5% per year in never smokers (95% CI, −2.2% to −0.8%) versus

−0.5% per year in ever smokers (95% CI, −1.0% to 0.01%) with a significant interaction ($P = 0.02$). There were no significant differences in the baseline effect by smoking status.

Discussion

Our results show, for the first time, that exposure to traffic particles, as indexed by BC, is associated with lower baseline lung function and accelerated lung function decline in the elderly, a population sensitive to the effects of particles. These effects were the same for participants younger and older than 65 years at baseline, and remained stable with increasing level of control for other potential predictors of lung function.

In 1965, Holland and Reid (16) showed that after controlling for smoking, lung function in long-term postal workers in London was lower than in similar postal workers in the countryside, where BC levels were roughly half of those in London. Since that time considerable research has indicated that air pollution in general, and particles specifically, are associated with lower lung function. Lubinski and coworkers (17) reported lower FEV_1/FVC ratios in nonsmoking Polish men on military entrance examinations were associated with particle concentrations in their home cities. Fewer studies have examined changes in lung function over time and most of them have focused on children. In Mexico City, reduced rates of lung function growth have been reported in children living in parts of the city with higher particle levels (18). The Southern California Children's Health Study followed children older than 8 years and found that $PM_{2.5}$ exposure was associated with clinically impaired lung function at 18 years of age (19). Avol and coworkers (20) identified 110 children from the University of Southern California Children's Health Study who moved from the study area, and followed them in their new home with pulmonary function testing identical to that in the main cohort. Subjects who moved to locations with higher PM_{10} concentrations had lower rates of annual growth in lung function, whereas children who moved to locations with lower PM_{10} levels showed higher rates of growth in lung function. This effect was larger in subjects who lived in the new location for at least 3 years. Another study took advantage of a natural experiment—the collapse of communism. Sugiri and coworkers (21) examined lung function in children in East and West Germany repeatedly between 1991 and 2000. In 1991 the West German children had higher lung function, and much lower exposure to particles. By 2000, changes in East German environmental and socioeconomic conditions had eliminated the difference in particle exposure, and the difference in lung function also disappeared.

In our study focused on elderly males, we found 1.3–6.7% lower levels of baseline lung function associated with previous exposure to BC. For each 0.5 $\mu g/m^3$ increase in long-term (1–5 yr) BC exposure, we found an additional annual rate of decline of 0.5–0.9% for FVC and 0.5–0.8% for FEV_1. In SAPALDIA, Downs and coworkers (3) reported 9% lower annual rates of decline in FEV_1 associated with a 10 $\mu g/m^3$ decrease in the annual average PM_{10} concentration between examinations. In ECRHS, Götschi and coworkers (22) found no significant effect of $PM_{2.5}$ on FEV_1 level and decline. The authors acknowledge such results might be caused by methodologic issues. In women, Sekine and coworkers (23) compared annual mean change of FEV_1 for three exposure groups older than 8 years and found stronger

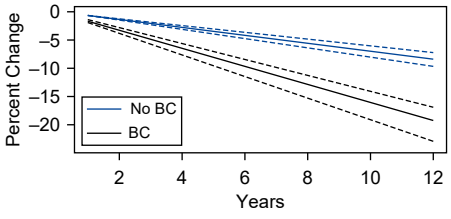

Figure 1. Rate of decline of FVC (and 95% confidence intervals [*dotted lines*]) comparing that seen at the mean black carbon (BC) in the study (0.5 $\mu g/m^3$) with what would have been expected in the counterfactual situation where BC was zero; 2,410 visits undergone by 858 men participating in the Normative Aging Study, 1995–2011.

FEV_1 decline in the group with the highest exposure to traffic. Comparison of results across studies is made difficult because of differences in exposure metrics and statistical methods used to study the relationship with lung function decline. In our study, the cross-sectional effects of BC were a bit stronger on FEV_1 compared with FVC, suggesting that BC exposure might lead to obstructive changes rather than restrictive. However, the longitudinal effects were slightly stronger on FVC compared with FEV_1. Further studies are needed to confirm whether traffic air pollutants affect lung function decline and to clarify whether such effect is more obstructive or restrictive.

We did not see any effect modification by FEV_1/FVC ratio, but we did see evidence of stronger effects in never smokers than in ever smokers, almost all of whom were former smokers. Former smokers often stop smoking because they become symptomatic, and it may be that the ability of air pollution to further damage already compromised lungs is limited, or that former smokers take action to limit their exposure. Further work is needed to first confirm this effect modification, and if confirmed, to identify the mechanism.

Hence, our main results are consistent with prior literature, but extend it to a key susceptible population, the elderly, and to a key fraction of particulate air pollution, traffic particles. BC is a marker of harmful combustion particles (24). In Boston, BC is a marker of traffic particles associated with local traffic and long-range transported traffic particles. Epidemiologic studies are supported by toxicology. For example, one study exposed mice and their offspring to either ambient air or filtered air to remove only particles, not gases. Lung function in the particle-exposed mice (average particles concentrations of 16.8 $\mu g/m^3$) was lower than in the mice with filtered air (average particle concentrations of 2.9 $\mu g/m^3$) (25). The underlying mechanisms of the association between air pollution and lung function are not fully elucidated. Pulmonary inflammation has been shown after controlled exposure to diesel exhaust, rich in BC and nitrogen oxides (26). Oxidative stress is a key pathway for pulmonary diseases, and a continuous reduction in oxidative stress in the lung has been shown in animals first exposed to the Boston air and then to a filtered air (27). Aging involves complex biologic phenomena. Physiologic functions can be compromised, making the elderly more susceptible to inflammatory states and vulnerable to air pollution. Particle clearance might be less efficient or impaired by other dysfunctions.

We acknowledge some limitations to our study. First, there is room for measurement error in BC exposure assessment, because we only accounted for home outdoor exposure as it is often the case in air pollution studies. By the time of our analysis, 75% of the men were older than 68 years, so essentially everyone was retired, making the home address a better location for assessing outdoor exposure than in a working population. Predictions from our land-use model have been merged to the geocoded address of each subject of the study and have been used to investigate the effect of traffic pollution on markers of inflammatory and endothelial response (28), blood pressure (29), cognitive function (30), and other outcomes. Because the elderly likely have reduced outdoor activities, indoor sources may contribute more to personal exposure than in other populations. Assuming that indoor and outdoor particles have the same composition and toxicity, Zeger and coworkers (31) have shown that errors caused by indoor exposures are of Berkson type, which is expected to increase standard errors. If indoor and outdoor particles are not

identical, then the effect would generally be underestimated.

Second, we cannot rule out residual or unmeasured confounding. However, we adjusted for a variety of potential predictors of lung function and our analyses indicated our results were robust. Furthermore, because we have seen associations of short-term exposure to traffic pollution with lung function (14), we controlled for BC averaged over the previous week (level 4) to ensure that we were really looking at an effect of long-term BC exposure. Cross-sectional effects of long-term exposure to BC were weaker when we adjusted for short-term exposure to BC, which means that part of the short-term effects of BC was previously captured by the cross-sectional effect of long-term exposure. Third, study results were observed in a cohort of elderly men, which may limit the generalizability of our results to similar populations.

The magnitude of the difference in lung function decline in the elderly is not trivial, and points to increased levels of significant impairment caused by the substantially greater decline in lung function among elderly men with higher exposure to traffic particles. Such effects should not be underestimated because they might be well-tolerated by a healthy population, but become life threatening for elderly or ill subjects (32). Moreover, particle pollution ($PM_{2.5}$) during the period of this study was always within the Environmental Protection Agency annual air quality standards. This indicates functionally significant differences in health and risk of disability occur within those standards. ■

Summary

Background Emerging evidence suggests that living near major roads might adversely affect cognition. However, little is known about its relationship with the incidence of dementia, Parkinson's disease, and multiple sclerosis. We aimed to investigate the association between residential proximity to major roadways and the incidence of these three neurological diseases in Ontario, Canada.

Methods In this population-based cohort study, we assembled two population-based cohorts including all adults aged 20–50 years (about 4·4 million; multiple sclerosis cohort) and all adults aged 55–85 years (about 2·2 million; dementia or Parkinson's disease cohort) who resided in Ontario, Canada on April 1, 2001. Eligible patients were free of these neurological diseases, Ontario residents for 5 years or longer, and Canadian-born. We ascertained the individual's proximity to major roadways based on their residential postal-code address in 1996, 5 years before cohort inception. Incident diagnoses of dementia, Parkinson's disease, and multiple sclerosis were ascertained from provincial health administrative databases with validated algorithms. We assessed the associations between traffic proximity and incident dementia, Parkinson's disease, and multiple sclerosis using Cox proportional hazards models, adjusting for individual and contextual factors such as diabetes, brain injury, and neighbourhood income. We did various sensitivity analyses, such as adjusting for access to neurologists and exposure to selected air pollutants, and restricting to never movers and urban dwellers.

Findings Between 2001, and 2012, we identified 243 611 incident cases of dementia, 31 577 cases of Parkinson's disease, and 9247 cases of multiple sclerosis. The adjusted hazard ratio (HR) of incident dementia was 1·07 for people living less than 50 m from a major traffic road (95% CI 1·06–1·08), 1·04 (1·02–1·05) for 50–100 m, 1·02 (1·01–1·03) for 101–200 m, and 1·00 (0·99–1·01) for 201–300 m versus further than 300 m (p for trend=0·0349). The associations were robust to sensitivity analyses and seemed stronger among urban residents, especially those who lived in major cities (HR 1·12, 95% CI 1·10–1·14 for people living <50 m from a major traffic road), and who never moved (1·12, 1·10–1·14 for people living <50 m from a major traffic road). No association was found with Parkinson's disease or multiple sclerosis.

Interpretation In this large population-based cohort, living close to heavy traffic was associated with a higher incidence of dementia, but not with Parkinson's disease or multiple sclerosis.

Funding Health Canada (MOA-4500314182).

Introduction

Dementia, Parkinson's disease, and multiple sclerosis are among the most common neurodegenerative diseases, with devastating effects on individuals, families, and society. Globally, about 55 million people have these disorders, with rising numbers expected given increasing longevity.[1,2] Without cures, identification of modifiable risk factors is important.

Despite the mounting global effect of these neurodegenerative diseases, their cause remains largely unknown.[3–5] Concern is growing that exposures associated with traffic such as air pollution and noise might contribute to neurodegenerative pathology.[6,7] Results of studies showed that air pollutants and diesel exhaust induce oxidative stress and neuroinflammation,[8] activate microglia,[9] and stimulate neural antibodies.[10] Exposure to more noise also impairs cognitive abilities in rats.[11] Similarly, a few epidemiologic studies[12–14] linked traffic-related noise and air pollution to cognitive decline and increased incidence of Parkinson's disease[15] and Alzheimer's disease.[16] Traffic exposure might affect various neurodegenerative processes.

Studies also showed that living near roads was associated with reduced white matter hyperintensity volume[17] and cognition,[18,19] but its effect on the incidence of dementia, Parkinson's disease, and multiple sclerosis is unknown. Living near traffic is a multifaceted exposure representing heightened exposure to nitrogen oxides, ultrafine particles, fine particulate matter (≤2·5 μm in diameter or $PM_{2.5}$), heavy metals, polycyclic aromatic hydrocarbons, volatile organic compounds, noise, and other factors. Because hundreds of millions of people

Research in context

Evidence before this study

We searched the MEDLINE and Embase databases for epidemiological studies of the associations between exposure to roadway traffic and the risk in adults (older than 18 years of age) of developing dementia, Parkinson's disease, or multiple sclerosis. Studies published in the peer-review literature up to Feb 1, 2016, were included, regardless of the language of publication. We perused the bibliographies of these articles and of previously published reviews. We searched the bibliographic databases using the keywords traffic exposure, mobile source, roadway, proximity or near, air pollution, and with the following health outcomes: dementia; Alzheimer's disease; cognition; Parkinson's disease; multiple sclerosis. A few studies found an association between living close to major roadways and cognitive decline and changes in the brain structure. There is also some evidence linking traffic-related noise and air pollution to cognitive decline and the incidence of dementia, and to a lesser degree, Parkinson's disease. No study has so far investigated the onset of all three major neurodegenerative diseases (dementia, Parkinson's disease, and multiple sclerosis) in association with near-road exposure. Moreover, the few existing studies involved relatively small study populations and nearly half were cross-sectional.

Added value of this study

We report that living close to heavy traffic is associated with increased incidence of dementia. Using the same populations and methods, however, we did not find an association between residential proximity to traffic and Parkinson's disease or multiple sclerosis. The cause of these major neurodegenerative diseases remains largely unclear. This study sheds important insights into a possible role of near-road exposure on the development of dementia. Our study overcomes several limitations of previous studies, since it has large cohorts comprising almost the entire adult population in Ontario, the most populous province in Canada, and lagged exposure up to 10 years to reduce concerns about reverse causality. With demographic characteristics similar to the USA and many European countries, findings from this study will be highly generalisable to populations in many other regions.

Implications of all the available evidence

Increasing population growth and continuing urbanisation globally has placed many people close to heavy traffic. With the widespread exposure to traffic and growing population with dementia, even a modest effect from near-road exposure can pose an enormous public health burden. This study suggests that improvements in environmental health policies and land use planning aimed at reducing traffic exposure can have considerable potential for prevention of dementia, which would lead to a broad public health implication. This study adds weight to previous observations suggesting that roadway traffic is an important source of environmental stressors that could give rise to neurological disorders and that future investigation targeting the effects of different aspects of traffic such as traffic-related air pollutants and noise on neurological health is merited.

worldwide live close to major roads, we sought to investigate the association between exposure to traffic, measured by residential proximity to major roadways, and the incidence of dementia, Parkinson's disease, and multiple sclerosis in a large population-based cohort in Ontario, Canada.

Methods

Study design

We did a population-based cohort study of all Ontario adults to determine the incidence of dementia, Parkinson's disease, and multiple sclerosis. Eligible participants were, as of April 1, 2001, Ontario residents for 5 years or longer, aged 20–85 years, and Canadian-born. We created the study population using Ontario's Registered Persons Database, a registry of all residents who have ever had health insurance. This database covers virtually all Ontario residents.[20]

Because dementia and Parkinson's disease onset occurs predominantly in people aged 55 years or older, whereas multiple sclerosis onset is most common in adults younger than 50 years, we separated the study population into two analytical cohorts: individuals aged 20–50 years (multiple sclerosis cohort); and individuals aged 55–85 years (dementia or Parkinson's disease cohort). We further excluded individuals with any of these three disorders at baseline, yielding a total of 4 372 720 and 2 165 268 participants in each cohort.

The Research Ethics Board of Sunnybrook Health Sciences Centre, Toronto, approved the study.

We ascertained incident diagnoses of dementia, Parkinson's disease, and multiple sclerosis using validated databases (see appendix). Details of these databases are available elsewhere.[20] These databases have been validated previously using chart review, with sensitivity of 78–84% and specificity of 99–100%.[21–23] They were created using hospital discharge abstracts from the Canadian Institute for Health Information, physician service claims from the Ontario Health Insurance Plan database, and prescription medication claims from the Ontario Drug Benefits programme database. Hospital, laboratory, and physician services in Ontario are funded by the provincial government through a single-payer universal medicare system that covers virtually all residents.[20] Drug coverage is provided to those aged 65 years or older, and social assistance recipients. We linked the cohorts to these databases using encrypted unique identifiers to ascertain incident cases.

See Online for appendix

Residential proximity to roads

We calculated residential proximity to major roadways or highways based on 6-character postal-code addresses in 1996, 5 years before cohort inception. Postal codes in urban areas represent the centroid of the blocks or single large buildings in which cohort members lived. Distance (m) was measured using ArcGIS. Major traffic roads include primary urban roads and arterial roads (ie, a major thoroughfare with medium to large traffic capacity with a combination of controlled access and intersections at grade level) whereas highways include expressways and primary and secondary highways, according to Ontario Government Road Network Data Standards. Consistent with previous studies,[17,24] we created five distance categories: less than 50 m from major traffic road, 50–100 m, 101–200 m, 201–300 m, and more than 300 m. We also considered a continuous measure of distance.

Data are n or %, unless otherwise specified. *Multiple sclerosis cohort comprised all adults aged 20–50 years and dementia/Parkinson's disease cohort comprised all adults aged 55–85 years in Ontario, Canada, in 2001. †In the 10 years before cohort onset. ‡From Canadian Census 2001, at the census dissemination area level.

***Table 1*: Baseline characteristics of the study population**

Covariates

We selected accepted or suspected risk factors for neurodegenerative pathology, including age, sex, pre-existing comorbidities, and socioeconomic status.[3–5] The comorbidities included traumatic brain injury, diabetes, hypertension, stroke, coronary heart disease, congestive heart failure, and arrhythmia. We ascertained the presence of comorbidities at baseline using hospital discharge abstracts, physician service claims, and validated chronic disease databases (appendix).

Several individual-level socioeconomic status and behavioural factors, such as education, smoking, and physical activity are also implicated in neurological health,[3–5] but were unavailable. Since neighbourhood-level socioeconomic status is strongly associated with these factors,[25,26] we derived four neighbourhood-level variables: income quintile, a measure of relative household income accounting for household size and community; percentage of population aged 15 years or older with less than high school education; unemployment rate; and percentage of recent immigrants, using 2001 Canadian Census dissemination area data. A dissemination area (with 400–700 people) is the smallest census geographic area for which census data are disseminated. We further derived neighbourhood-level deprivation based on the Ontario Marginalization Index that quantifies the degree of marginalisation in health and social wellbeing (appendix).

To control for regional differences in the incidence of dementia, Parkinson's disease, and multiple sclerosis, we created a variable for urban residence (yes/no), density of neurologists using the ICES Physician Database to represent accessibility to neurological care, and the latitude of residence given the reported latitude gradient with multiple sclerosis.[3] Additionally, we created a dichotomous variable classifying Ontario into the Greater Toronto Area, a densely-populated urban mega-region, and all other areas. Toronto tends to differ from other areas with respect to sociodemographic characteristics, health care access, and population health status.

To explore whether exposure to air pollutants, especially nitrogen dioxide (NO_2) and $PM_{2.5}$ might explain the roadway proximity-outcome association, we obtained long-term measures of $PM_{2.5}$ and NO_2 for all participants (appendix). Briefly, estimates of ground-level concentrations of $PM_{2.5}$ were derived from satellite observations of aerosol optical depth in combination with outputs from a global atmospheric chemistry transport model (GEOS-Chem CTM).[27] The $PM_{2.5}$ estimates were further adjusted using information on urban land cover, elevation, and aerosol composition using a geographically weighted regression. We used estimates between 1998 (the earliest year with available data) and 2001 (the year of cohort inception), thus producing four-year mean concentration of $PM_{2.5}$ at a spatial resolution of 1×1 km and covering all North America

Cox proportional hazards model with age as the time-scale, stratified by an indicator for living in the Greater Toronto Area or not, adjusted for sex, history of diabetes, hypertension, coronary heart disease, stroke, congestive heart failure, arrhythmia, and traumatic brain injury, income quintile, urban/rural indicator, census division-level unemployment rate, education, recent immigrants, as well as the subtraction of these variables at the census dissemination level from their census division. For multiple sclerosis, the model was also adjusted for latitude. †Major traffic roads include primary urban roads and arterial roads whereas highways include expressways and primary and secondary highways, as defined by Ontario Government Road Network Data Standards. ‡Incidence of dementia and Parkinson's disease was analysed among all adults aged 55–85 years (dementia/Parkinson's disease cohort) whereas incidence of multiple sclerosis was analysed among all adults aged 20–50 years (multiple sclerosis cohort). §Distance was fitted as a continuous variable, using natural logarithm of distance. Hazard ratios (HRs) expressed per IQR increase in distance (dementia/Parkinson's disease cohort: 310 m and multiple sclerosis cohort: 320 m).

***Table 2*: Hazard ratios and 95% CIs for the associations between residential proximity to major roadways in 1996 and the risks of incident dementia, Parkinson's disease, and multiple sclerosis in Ontario, during the follow-up period 2001–12**

below 70°N, which includes all of Ontario. These satellite-based estimates of $PM_{2.5}$ closely agree with ground measurements at fixed-site monitoring stations across North America (R^2 0·82, n=1440).[27] Similarly, we derived long-term exposure to NO_2 from a national land-use regression (LUR) model developed from Environment Canada's National Air Pollution Surveillance Network monitoring data, 2005–11 satellite NO_2 estimates, area of industrial land use, road length, and mean summer rain fall.[28] The estimates were further calibrated by incorporating local-scale variations of NO_2 from vehicle emissions by applying spatially-varying multipliers that represented distance-decay gradient in NO_2. The final LUR model explained 73% of the variation in annual 2006 measurements of NO_2, with a root mean square error of 2·9 parts per billion (ppb).[28] The resulting LUR NO_2 estimates were available for each year between 1998 and 2001, after applying temporal adjustment.

Statistical analysis

We used Cox proportional hazards models with age as the time-scale to assess the relationship between residential proximity to major roadways and the incidence of dementia, Parkinson's disease, and multiple sclerosis. For each outcome, follow up time (in days) was measured from April 1, 2001 until diagnosis date, ineligibility for provincial health insurance, death, or March 31, 2012.

Separate models were developed for each disease. All models were stratified by region (living in Toronto or not), and adjusted for sex, comorbidities, urban residency, and neighbourhood-level income, education, unemployment, and immigration status. To adjust for regional variations in the neighbourhood-level variables across Ontario, we included them as the average for each census division (equivalent to county), and as the difference between the values for each census dissemination area and the census division mean. We further adjusted for latitude for multiple sclerosis cohort. The analyses were repeated using distance as categorical and continuous variables.

We routinely tested for deviation from the proportional hazards assumption by adding the cross-product of each variable with the natural logarithm of the time variable, but we did not find any violation of this assumption (p>0·05). We calculated adjusted hazard ratios (HRs) and 95% CIs for each category of roadway proximity compared with the furthest category (>300 m). Linear trend was assessed by assigning the median distance (in natural log) to each category and fitting the term as a continuous variable in a regression model. In analyses with distance as a continuous variable, we considered the natural log of distance because this exposure has been linearly related to mortality and morbidity outcomes in Ontario and elsewhere.[17,24]

Sensitivity analyses

We controlled for access to neurologists, deprivation index, and a North/South indicator (appendix). We also adjusted for a linear term for time to account for potential changes in the risk of the three disorders over time.

We assessed whether HR might be influenced by any spatial dependence among participants. We fitted models with a frailty term for census division (ie, county) to account for the possibility that participants in the same community could share similar risk factors than those living in different locations. We assumed a gamma distribution for the frailties, with an exchangeable correlation structure within county.

We assessed the potential influence of unmeasured individual-level socioeconomic status and behavioural variables, especially education, smoking, obesity, and

Indirect adjustment for smoking and physical activity for Parkinson's disease, and for smoking for multiple sclerosis. Data of smoking and physical activity were obtained from Ontario respondents to the 1996 cycle of National Population Health Survey and the 2000–01 and 2003 cycles of Canadian Community Health Survey. For Parkinson's disease, respondents aged 50–85 years at the time of the surveys were included (n=16 441) and for multiple sclerosis, those who were 20–55 years old were included (n=31 635). †Major traffic roads include primary urban roads and arterial roads whereas highways include expressways and primary and secondary highways, as defined by Ontario Government Road Network Data Standards. ‡Cox proportional hazards model with age as time axis, stratified by an indicator for living in the Greater Toronto Area or not, adjusted for sex, history of diabetes, hypertension, coronary heart disease, stroke, congestive heart failure, arrhythmia, and traumatic brain injury, income quintile, urban/rural indicator, census division-level unemployment, education, and recent immigrants, as well as the subtraction of these variables at the census dissemination level from their census division. ***Table 4*: Hazard ratios and 95% CI for associations between residential proximity to major roadways in 1996 and risk of incident Parkinson's disease and multiple sclerosis in Ontario, during the follow-up period 2001–12**

physical activity on our results. To do this, we used a method to mathematically adjust HR for these variables while simultaneously controlling for all variables available in the model (ie, age, sex, comorbidities, and socioeconomic status; appendix). Details of this method are presented elsewhere.[29] Briefly, this method requires spatial associations between the unmeasured and observed variables from an auxiliary dataset. Following previous Canadian studies,[30] we obtained the relationships using data from the 1996–97 cycle of the National Population Health Survey and the 2000–01 and 2003 cycles of the Canadian Community Health Survey, which constituted a representative sample of the study cohorts (appendix). This information along with estimated associations between these unmeasured variables and incident dementia, Parkinson's disease, and multiple sclerosis from the literature, were used to estimate their effect on HR. Based on systematic reviews of dementia, Parkinson's disease, and multiple sclerosis, we considered all four variables in our analysis with dementia, smoking and physical activity with Parkinson's disease, and smoking with multiple sclerosis (appendix).

Furthermore, we additionally adjusted for $PM_{2·5}$ and NO_2, excluded events occurring in the first 2 and 5 years

during follow-up to lag exposure up to 10 years, excluded people residing in long-term care facilities (often located near major roadways) at baseline, and restricted the dementia/Parkinson's disease cohort to those aged 65 years or older because drug information was unavailable for younger adults. Lastly, we further adjusted for rurality index and neighbourhood-level percentage of visible minority, and restricted the analysis to people who never moved since 1996, to urban residents, and to residents of six major urban centres in Ontario (Toronto, Hamilton, Ottawa, London, Windsor, and Sarnia) (appendix).

Role of the funding source

The funder had no role in study design, data collection, data analysis, data interpretation, or writing of the report. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Results

The multiple sclerosis cohort comprised 46·7 million person-years of observations and the dementia/Parkinson's disease cohort contributed 20·1 million person-years. At baseline, the mean age was 35·9 years (SD 8·7 years) for the multiple sclerosis cohort and 66·8 years (8·2 years) for the dementia/Parkinson's disease cohort (table 1). Of the multiple sclerosis cohort, 50% were male, 17% were rural residents, 2% had diabetes, and 7% had hypertension, whereas 47% of the dementia/Parkinson's disease cohort were male, 19% were rural residents, 15% had diabetes, and 48% had hypertension. Average unemployment among census dissemination areas was 6% and the mean percentage of population with less than high school education was about 26% in both cohorts.

Nearly half of the cohorts lived within 200 m from a major road and 95% were within 1000 m (appendix). Of the cohorts, the average concentration of $PM_{2.5}$ according to participants' residences in 1996, 5 years before cohort inception, was 9·7 μg/m³ (range 1·3–19·8 μg/m³), while the average concentration of NO_2 was 15·4 ppb (2·2–62·0 ppb). Between 2001–12, we identified 243611 incident cases of dementia, 31577 incident cases of Parkinson's disease, and 9247 incident cases of multiple sclerosis.

In both categorical and continuous analyses, living closer to a major road was associated with increased incidence of dementia, with fully adjusted HR of 1·07 (95% CI 1·06–1·08) for people living less than 50 m, 1·04 (1·02–1·05) for people living 50–100 m, 1·02 (1·01–1·03) for people living 101–200 m, and 1·00 (0·99–1·01) for people living 201–300 m away from a major roadway versus more than 300 m from a major roadway (P_{trend}=0·0349; table 2). An interquartile-range increase in residential proximity to a major road was associated with a 9% (95% CI 8–11%) lower incidence of dementia. In contrast, there was no evidence linking traffic proximity to Parkinson's disease or multiple sclerosis (HR 1·00 for both; table 2).

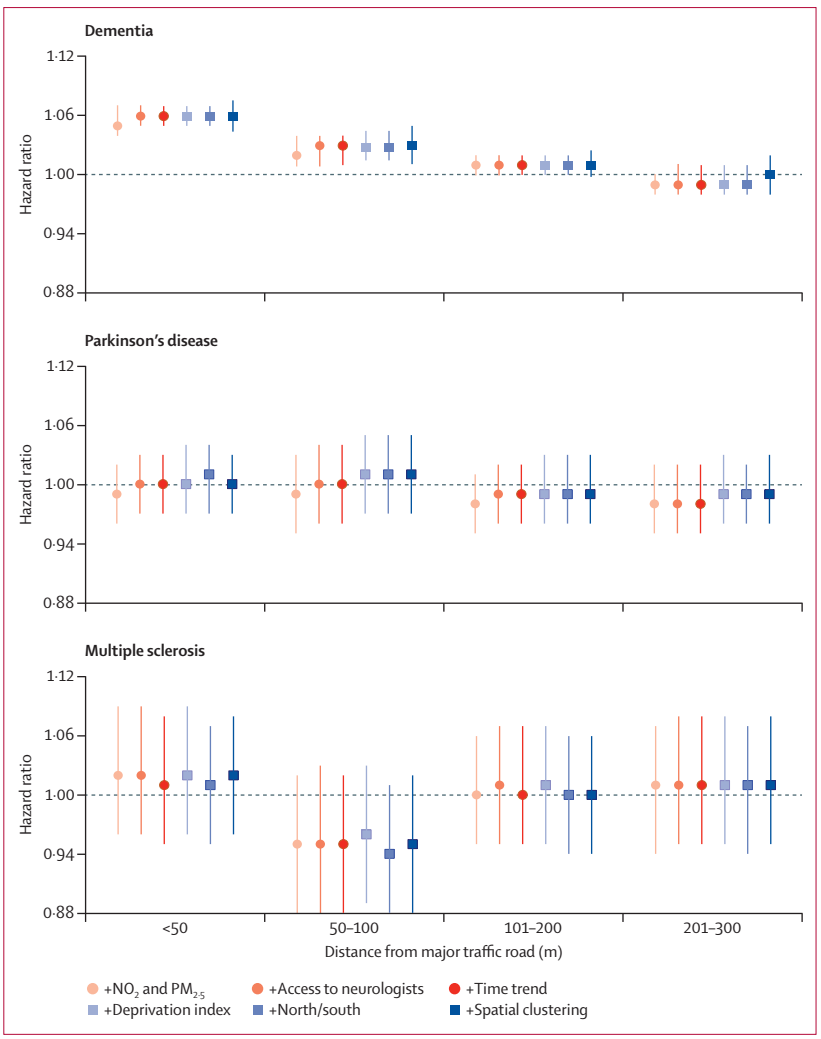

***Figure 1*: Estimated associations between residential proximity to major roadways in 1996 and the risk of incident dementia, Parkinson's disease, multiple sclerosis in Ontario, 2001–12**
Measured by six sensitivity analyses to further control for potential confounding factors. Model further adjusted for exposure to NO_2 and $PM_{2.5}$ access to neurologists, time trend, deprivation, an indicator for North/South Ontario, and a frailty term to account for potential spatial clustering.

The association between traffic exposure and dementia was insensitive to additional controls for smoking, obesity, physical activity, and education (HR 1·06 for living <50 m away from a major road, 1·04 for 51–100 m, and 1·02 for 101–200 m; table 3). Similarly, the associations between traffic exposure and Parkinson's disease and multiple sclerosis remained unchanged after adjusting for smoking and physical activity (table 4).

Further adjustment for access to neurologists, deprivation, time trend, and a North/South indicator did not alter the associations, nor did adding a frailty term in the survival model to account for potential spatial clustering (figure 1). Adjustment for NO_2 and $PM_{2.5}$ modestly attenuated the association between traffic

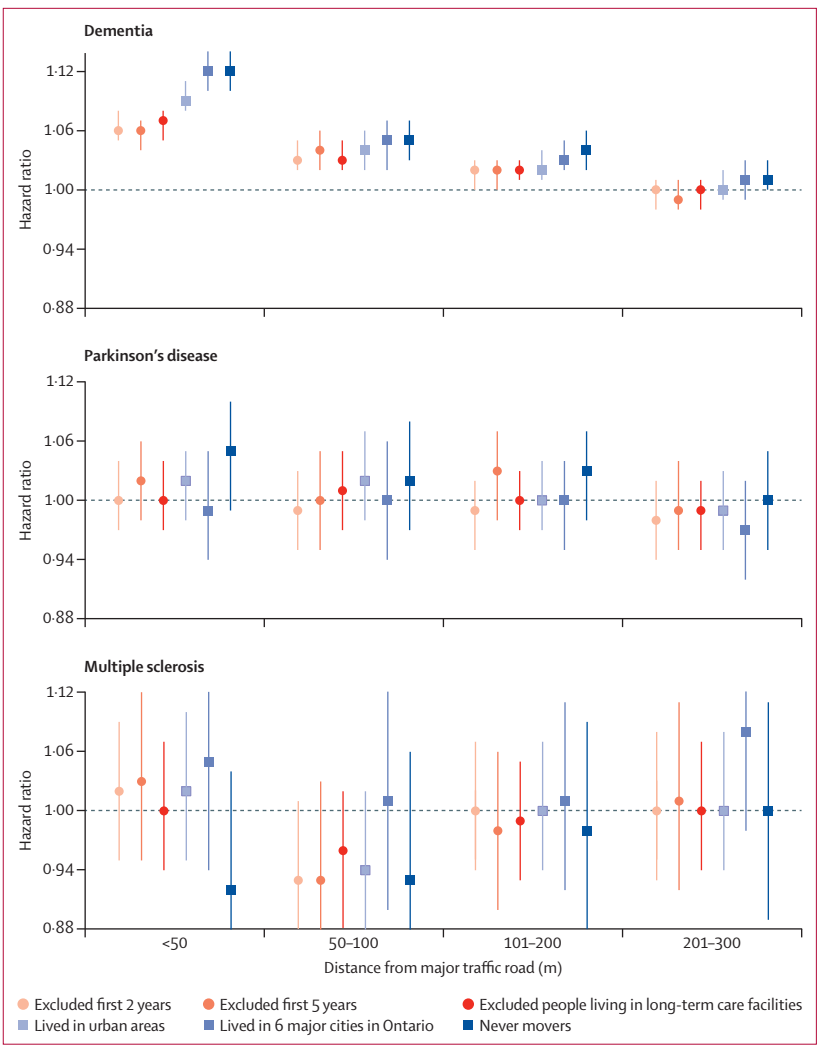

***Figure 2*: Association between residential proximity to major roadways in 1996 and the risk of incident dementia, Parkinson's disease, multiple sclerosis in Ontario, 2001–12**
Hazard ratios and 95% CIs from six additional sensitivity analyses (excluding first 2 years of follow-up, excluding first 5 years of follow-up, excluding people living in long-term care facilities, restricting to urban residents, restricting to six major cities in Ontario, and restricting to those who did not move after 1996).

proximity and dementia (HR 1·05 for living <50 m away from a major road and HR 1·02 for 51–100 m away from a major road *vs* 1·07 and 1·04 without adjustment). Importantly, NO_2 was significantly associated with dementia, whereas $PM_{2.5}$ was associated with both dementia and Parkinson's disease (appendix).

In sensitivity analyses, the magnitude of associations were similar after further excluding the first 2 and 5 years of follow-up, restricting to people aged 65 years or older, excluding those living in long-term care facilities, or considering other sensitivity analyses (figure 2 and appendix). However, the association between living less than 50 m from a major roadway and dementia appeared stronger among participants who lived in urban areas, who lived in one of the six major cities, or who never moved (HR 1·09–1·12, depending on the analysis).

Discussion

In this large population-based cohort, living near major roadways was associated with increased dementia incidence. The associations seemed stronger among urban residents, especially those living in major urban centres and those who never moved. Although the increase in risk might appear moderate (eg, HRs varied from 1·07–1·12 for living <50 m away from a major road, depending on the region), this translates to 7–11% of dementia cases in patients who live near major roads attributable to traffic exposure (appendix). The associations were robust to various sensitivity analyses, except for additional adjustment for $PM_{2.5}$ and NO_2 which led to a modest attenuation. It is noteworthy that both NO_2 and $PM_{2.5}$ were positively associated with dementia. Lastly, we found no association between roadway proximity and incidence of Parkinson's disease or multiple sclerosis.

To our knowledge, this is the first study to investigate the onset of three major neurodegenerative diseases in association with near-roadway exposure. Previous studies have linked living near roadways to cognitive decline in cohorts of older adults in Boston MA, USA[18] and in the Ruhr area, Germany,[19] and to smaller white matter hyperintensity volume in the Framingham Offspring cohort.[17] Living near major roads substantially increases an individual's exposure to traffic-related air pollution (eg, ultrafine particles, nitrogen oxides, and particles from wear of tyres and friction materials), and noise.[17] Although the mechanisms through which traffic exposure might affect brain health are unknown, systemic inflammation arising from traffic-related air pollution is probably important. In studies of both experimental animals and in autopsy samples of sudden accidental deaths in human beings, particulates and diesel exhaust provoke oxidative stress and systemic inflammatory responses, disrupt the blood-brain barrier, precipitate Aβ peptides, and activate microglia.[8,9] Ultrafine particles have also been found in the olfactory bulb and the frontal cortical areas in the brain of highly exposed dogs and human beings.[8] Furthermore, emerging epidemiologic evidence relates nitrogen oxides and black carbon, markers for traffic-related pollution, to dementia incidence[12] and cognitive impairment.[14] We observed that exposures to NO_2 and $PM_{2.5}$ were related to dementia and that adjusting for these two pollutants attenuated its association with roadway proximity, suggesting that the effect of traffic exposure might, at least in part, operate through this mechanism. Given the potentially significant implications of exposure to traffic-related pollutants on dementia risk, understanding their effects merit further investigation.

The fact that $PM_{2.5}$ and NO_2 did not fully explain the near-road effect on dementia suggests that additional pollutants or other factors such as noise might play a role. Although we were unable to directly examine these factors, traffic-related noise has been linked to cognitive

impairment in a cohort in Germany.[13] In rat models, noise exposure directly impaired cognition.[11] Additionally, sleep loss from noise contributes to sleep fragmentation, which is associated with reduced cognition.[5] Living near busy roads might also reduce physical activity, which could subsequently affect neurological health. However, we found little change in our results after indirect adjustment for this variable.

Compared with dementia, less is known about the effect of traffic exposure on Parkinson's disease and multiple sclerosis. Only three studies have examined the relationship between traffic exposure and Parkinson's disease: a positive association between NO_2 and incident Parkinson's disease was reported in a case-control study in Denmark,[15] whereas in another case-control study in the USA, no association with NO_2 was found.[31] Additionally, in a cross-sectional study in Ontario, Parkinson's disease prevalence was not associated with roadway proximity nor NO_2.[32] For multiple sclerosis, one time-series study found a relationship between daily hospital admissions and particulate pollution,[33] but no studies have assessed the effect of living close to traffic. In this study, we observed an association only between traffic proximity and dementia, which might be attributable to relatively few cases of Parkinson's disease and multiple sclerosis. Another possibility is that traffic exposure could augment neurodegeneration through pathways that are related to dementia but not Parkinson's disease or multiple sclerosis.[3–5]

Our study has some limitations. First, we could not identify undiagnosed cases of dementia, Parkinson's disease, and multiple sclerosis. However, the estimates were unchanged when we adjusted for access to neurologists, a North/South indicator, deprivation, and time trends. With universal health care in Ontario, incomplete diagnosis might lead to underestimation of the true effect because this measurement error was probably independent of the exposure.

Second, we did not have information on medications that might potentially influence dementia risk (eg, anti-inflammatory medication and NSAIDs), although it is unclear whether these factors would be associated with traffic exposure. Furthermore, we lacked information on individual socioeconomic status and behavioural variables. To control for these unmeasured variables, we adjusted for neighbourhood socioeconomic status and comorbidities. Since neighbourhood socioeconomic status is strongly associated with individual socioeconomic status and behavioural variables,[25,26] and comorbidities and neurodegenerative diseases share some common behavioural factors, adjusting for these variables should reduce the influence of these unmeasured variables on HR (appendix). We further controlled indirectly for these variables, and found similar results. Although we cannot rule out residual confounding, the null findings for Parkinson's disease and multiple sclerosis do not support this possibility.

Third, our exposure assessment was based on postal-code addresses, which do not completely reflect personal exposure. $PM_{2.5}$ is a complex mixture with a secondary aerosol component that might not originate from vehicle emissions. Finally, roadway proximity does not account for traffic density and meteorological conditions that might influence exposure to air pollution and noise. Given the inherent imprecision of this exposure, our assessment of near-road exposure was probably subject to non-differential misclassification that probably attenuated our results.

The strengths of this study include the large cohorts made up of almost the entire adult population in Ontario. The many cases ascertained from validated registries enabled us to investigate fine-scale changes in traffic exposure and to examine the effect from exposures lagged up to 10 years. Our study also benefited from quantifying and comparing the effects on three major neurodegenerative diseases from traffic exposures using the same methods. Furthermore, the availability of detailed information on medical and residential history allowed us to control for important risk factors (eg, head trauma) and assess the influence of residential mobility.

Conclusions

In this large cohort, living near major roadways was associated with higher incidence of dementia, but not Parkinson's disease or multiple sclerosis. Given the potentially significant implications of traffic exposure on dementia risk, understanding the effect of different aspects of traffic merits further investigation.

Executive Summary

INTRODUCTION

This report presents the final consensus resulting from nine months of deliberations by a broad-based group appointed by I-710 corridor communities and the I-710 Oversight Policy Committee. Known as the Tier 2 Committee, this group represented a broad base of interests, including local communities, academic, environmental, business, community and environmental justice. The most directly impacted communities in the corridor were invited to form community-level committees (known as the Tier 1 Committees). The chairs of these committees were also represented on the Tier 2 Committee, along with a representative named by each City Council in the remaining corridor cities.

The following guiding principles define the priorities of the Tier 2 Committee and reflect the consensus that emerged during this process:

1. **This is a corridor – considerations go beyond the freeway and infrastructure.**
2. **Health is the overriding consideration.**
3. **Every action should be viewed as an opportunity for repair and improvement of the current situation.**

The Committee recognizes that something must be done to address the current congestion and design of the I-710 freeway. The high number of trucks on the freeway uses up capacity and the mix of cars and trucks poses a serious safety concern. The committee agrees that the hybrid design concept presented could accomplish maximum build out in a manner that reflects the Tier 1 CACs' concerns and recommendations for their communities, with the exception of the City of Commerce and East Los Angeles area, which require further study. However, the I-710 corridor is more than just a place for trucks to pass through on their way to their final destination. It is the location of our homes, businesses, schools, parks, and lives. Today, particulates and other pollutants from diesel truck traffic in the I-710 Corridor and the ports of Long Beach and Los Angeles are our communities' primary air-quality-related health concern. **Therefore, the conditions for major infrastructure improvements must be as follows:**

1. Implement a corridor level action plan to improve community air quality.
2. Major infrastructure improvements must be conditioned on achieving air quality goals to protect public health; corridor air quality must comply with county, state and federal standards prior to the start of mainline construction

and the entire project taken as a whole must result in a net reduction in criteria pollutants.

3. Prior to the initiation of the environmental review process, all Tier 1 Community Advisory Committees must have formally endorsed the freeway improvement design concept.

4. Prior to adopting a preferred alternative the OPC must conduct a study and cost benefit analysis of potential goods movement alternatives as an alternative to increasing the capacity of the I-710 Freeway.

5. A study of the impact of construction on air quality, traffic, congestion, noise and impact on surrounding communities must be conducted, and if construction does go forward, specific mitigation plans must be developed and put into effect during the construction process to minimize and mitigate the impact of construction on the surrounding communities.

6. Major infrastructure improvements must be conditioned on achieving a net decrease in noise impacts upon the affected communities.

The Committee recognizes that certain aspects of the design concepts, particularly for designated on-ramps, may be appropriate for implementation prior to addressing the "mainline" issues. However, these improvements cannot be constructed in isolation from all of the other recommendations such as public health, community enhancement, and noise abatement. The I-710 design must take into account the safety and quality of life of the communities in the corridor, including provisions for greenbelts and open space.

This Executive Summary presents a synopsis of our committee's findings and recommendations, which are presented, in eight topic areas. (Greater detail is provided in the full report.)

HEALTH

Air quality is the number one public health issue. Poor air quality has had significant negative impacts on public, economic, environmental and community health in the corridor. Particulates and other pollutants from diesel truck traffic in the I-710 Corridor and the ports of Los Angeles and Long Beach are our communities' primary air-quality-related health concern. The first consideration for approval of any improvements within the I-710 corridor must be the project's ability to reduce air quality impacts. Therefore, these steps must be taken before construction can begin on the "mainline" project to reduce air pollution.

The Tier 2 Committee recommends the following air quality improvement strategies:

1. Develop an action plan to improve air quality in the corridor.
2. Implement a corridor level action plan to improve community air quality.
3. Implement local alternative fuels/electrification and/or hydrogen policies and programs to reduce diesel emissions.
4. Pursue opportunities for incremental improvements.
5. Implement port-specific air quality improvement strategies.

JOBS AND ECONOMIC DEVELOPMENT

The twin ports of the San Pedro Bay generate significant economic benefits for the region as a whole. However, the cost associated with the movement of goods is primarily borne by local communities. These external costs, including increased levels of pollution, have reduced the attractiveness and livability of these communities. To address this imbalance, local residents and businesses must become net beneficiaries of the continued growth in international trade through the local ports. Improvement of air quality and the environment are essential for the area to take advantage of and capitalize on the area's assets. In addition, an investment in education is necessary to continue to diversify the economy and provide economic opportunity for residents.

The Tier 2 Committee recommends the following economic development strategies:

1. Position the I-710 corridor and Gateway communities for a post-oil economy.
2. Create a community environment that attracts and retains businesses and residents who can support a new gateway cities economy.
3. Enable the I-710 corridor and Gateway communities to become more proactive in today's economy.
4. Institute corridor-wide programs and partnerships to equip area residents with the skills needed to move into higher-paying jobs in this new economy.
5. While promoting the importance of all business, specifically recognize small business as an economic driver and foster its growth within the communities.
6. Consistent with current law, advocate policies at the national, state, regional and local levels to require businesses that benefit from any potential I-710 improvements to pay living wages.

SAFETY

The I-710 corridor is one of the most unsafe freeways in the State. Increasing truck traffic, conflicts between cars and trucks, aging infrastructure, and outdated design are all contributing causes to accidents in and around the freeway. The high concentration of older trucks, which frequently become disabled, poses a significant safety hazard, as do truck intrusions into nearby communities and neighborhoods. Just as the Alameda Corridor helped reduce conflicts between trains and automobiles, any improvements to the I-710 corridor must resolve the inherent conflicts between automobiles and trucks.

The Tier 2 Committee recommends the following safety improvement strategies:

1. Continue support and implementation of safety programs.
2. Increase enforcement of traffic and vehicle safety laws and regulations.
3. Increase public and trucker education on safety and neighborhood issues.
4. Implement infrastructure improvements.
5. Separate trucks and cars.

NOISE

Excessive noise is a serious public health concern in the corridor and cannot be resolved by simply building more sound walls. A comprehensive analysis of noise along the corridor must lead to a plan that recognizes the health impacts to our communities and seeks to resolve those impacts by providing appropriate relief. Major infrastructure improvements must be conditioned on achieving a net decrease in noise impact upon the affected communities.

The Tier 2 Committee recommends the following noise control strategies:

1. Provide appropriate and effective sound walls to reduce noise impacts to neighborhoods and schools adjacent to the freeway.
2. Implement noise mitigation programs.
3. Conduct a study to assess how truck traffic from extended gate hours for trucks and 24/7 port operations will impact communities, and assess what mitigations may be appropriate.

CONGESTION AND MOBILITY

The major purpose of congestion relief must be to improve the quality of life and economic vitality of the corridor rather than simply to accommodate port growth. The current corridor capacity is not adequate even for the existing demands in the area. The current conditions along the corridor are simply not acceptable. The Committee suggests an approach that provides multiple options for personal mobility – auto, pedestrian, bike and transit – within the corridor. Likewise, goods movement requires a comprehensive, regional approach that reduces bottlenecks in all segments – ship, truck, and rail.

The Tier 2 Committee recommends the following congestion and mobility strategies:

1. Maximize use of existing infrastructure
2. Implement expanded public transit solutions.
3. Provide a comprehensive bicycle and pedestrian network with connectivity throughout the area.
4. Develop a consistently implemented plan with cities and residents to mitigate construction impacts and maintain access.
5. Support cooperative planning among all ports along the West Coast.

COMMUNITY ENHANCEMENTS

The I-710 corridor is more than just a place for trucks to pass through on their way to their final destination. It is the location of our homes, businesses, schools, parks, and lives. Plans for future improvements to the I-710 are not intended to solely address congestion and mobility problems. Instead a revitalized I-710 must be the catalyst to enhance local communities along the corridor, creating an even more desirable place to live, work, and play. Major infrastructure improvements must also be conditioned on conclusion of satisfactory agreements with the neighboring communities to fully mitigate negative aesthetic impacts and to mitigate the impacts of any increased light and glare.

The Tier 2 Committee recommends the following community enhancement strategies:

1. Preserve existing parks, open space, and natural areas.
2. Develop and implement community enhancement projects.
3. Provide programs to minimize construction impacts.
4. Develop and implement a plan for arterial streetscapes.
5. Mitigate light and glare in surrounding communities.

DESIGN CONCEPTS

A new design concept for I-710 and/or alternative transportation modes for vehicles and goods movement is needed that responds to the specific design recommendations developed by the Tier 1 CACs to minimize or limit take of homes within their communities along I-710. The hybrid design, as developed to date, does a credible job of accomplishing this goal. However, final decisions on project configuration can only be made subsequent to incorporation of the further study of East Los Angeles and City of Commerce and upon completion of cost benefit and environmental studies. The I-710 design must take into account the safety and quality of life of the communities located next to the freeway, including provisions for greenbelts and open space.

The Tier 2 Committee recommends the following design concept strategies:

1. Endorse the specific Tier 1 CAC recommendations included in the Appendix.
2. Support capacity enhancement improvements for the I-710 Freeway upon meeting the conditions recommended in this report, including those recommended by both Tier 1 and Tier 2 CACs.
3. If economic and environmental studies show that expansion of the freeway is necessary, develop new transportation infrastructure for I-710 that separates cars from trucks.
4. If economic and environmental studies show that expansion of the freeway is necessary, locate the new truck lanes in such a way as to minimize community impacts.
5. Redesign unsafe and congested interchanges on I-710.
6. Consider future needs and requirements in implementing any new I-710 design.
7. If economic and environmental studies show that expansion of the freeway is necessary, upgrade of the existing freeway must satisfy criteria detailed in this report.

ENVIRONMENTAL JUSTICE

In the fifty years since the freeway was first built, the corridor has become home to minority and low-income populations. For many years, the people who live within the corridor have shouldered an unfair burden in health, economic, and quality of life issues. Environmental justice requires a mechanism for the meaningful involvement of all people in the transportation decision-making process and to ensure that the low-income and

minority communities receive equitable distribution of the benefits from transportation activities without suffering disproportionate adverse impacts.

The Tier 2 Committee recommends the following environmental justice strategies:

1. Include the corridor communities in the planning process in a meaningful way, including provision of appropriate language translation.
2. Ensure that impacts do not disproportionately fall on low-income people or people of color.
3. Ensure that the benefits from the projects flow to the corridor communities.

ORGANIZATION AND PROCESS

To ensure that the work of the Tier 2 Committee is carried forward as set forth in the full report, a task force of representatives from the Tier 2 CAC, the OPC and the TAC should be established to plan and oversee the implementation of the conditions and recommendations of the Tier 2 CAC.

The Tier 2 Committee recommends the following organization and process strategies:

1. This Tier 2 Report will be formally "agendized" and presented to the OPC when it convenes in September 2004 for its consideration and decision. All Tier 2 members will be invited to the OPC meeting, and the presentation of the Tier 2 report will be delivered by a representative group of Tier 2 spokespersons.
2. Following the OPC's meeting, there will be a follow-up meeting(s) of the Tier 2 Committee to discuss actions taken by the OPC.
3. Prior to the beginning of any formal EIR for the I-710 Major Corridor Study, Metro (MTA) and the Gateway Cities COG will work with the communities, appropriate agencies, organizations and community groups in developing a collaborative process for community participation in the environmental review process. This process will continue to work collaboratively throughout the EIR process.

CONCLUSIONS AND NEXT STEPS

This report is hereby presented by the Tier 2 CAC to the I-710 Oversight Policy Committee. The Committee expects that its recommendations will be carried forward by the OPC, the Gateway Cities COG, the Los Angeles County Metropolitan Transportation Authority (Metro), the Southern California Association of Governments (SCAG) and the

California State Department of Transportation (Caltrans). Further, we expect our recommendations to be used as required guidance in the planning and development of future corridor improvements. The Committee and the communities we represent expect to have continued formal and meaningful participation in the I-710 corridor improvement process and look forward to working with the OPC and future project sponsors toward an improved and revitalized I-710 Corridor.

I. Introduction

This report documents the recommendations for policies, strategies and conditions developed by the Tier 2 Committee to address I-710 issues, paving the way for a consensus-based corridor solution. The Tier 1 Community Advisory Committee (CAC) chairs represented the Tier 1 Committees on the Tier 2 Committee to ensure that community concerns and recommendations were represented. The Oversight Policy Committee (OPC) will review the findings and recommendations outlined in this report and will use the information to make recommendations for potential action. The Technical Advisory Committee (TAC) will review the recommended strategies generated by the process and consider the implications to the local preferred strategy. This report will also be included in the Major Corridor Study.

Strategic discussions among Tier 2 Committee members occurred over a series of twelve facilitated meetings held from February through August 2004. Building on a foundation of understanding of their own community issues and particular concerns, Tier 2 Committee members began to examine corridor-wide issues and shared their viewpoints with each other in open and thought-provoking dialogues. Experts were available to answer questions and to add clarity to specific concerns.

GUIDING PRINCIPLES

The Foundation of Our Findings

The guiding principles set forth below affirm the Tier 2 Committee's concerns and encompass the values that are important to the communities along the corridor. These principles define the priorities of the Tier 2 Committee and reflect the consensus that emerged during this process. The recommendations in this report support these principles:

1. This is a corridor – considerations go beyond the freeway and infrastructure.
2. Health is the overriding consideration:
   - Public Health (the people)
   - Environmental and Community Health (the place)
   - Economic Health (the resources)
3. Every action should be viewed as an opportunity for repair and improvement of the current situation.

II. Financial Considerations

The Committee recognizes that the strategies, recommendations and conditions in this report will be costly. In order to implement the strategies and policies identified by the Tier 2 Committee it will be necessary to establish appropriate lead agencies and funding sources for these programs. This Committee expects that the project lead agency will be responsible for directing mitigation funds to implement these recommendations. While it is expected that mitigation funds and fees may fund all or portions of these programs, the issues of funding and program implementation are generally beyond the scope of these recommendations and must continue to be addressed by the Tier II CAC and OPC. The Committee also expects that our public officials will bring to bear all available means to implement the community's vision including existing and new regulations, incentives, and funding sources, including appropriate contributions from the goods movement industry

III. Conditions

1. Implement a corridor level action plan to improve community air quality. The State shall levy fees on containers to fund environmental improvements and community programs to address hidden costs attributable to goods movement impacts, including the funding of community health care clinics.

2. Major infrastructure improvements must be conditioned on achieving air quality goals to protect public health. Based on air monitoring data collected by regional air quality agency stations (including, but not limited to, South Coast Air Quality Management District (AQMD) stations in Lynwood and North Long Beach), corridor air quality must be in compliance with State and National Ambient Air Quality Standards prior to the start of freeway construction. Furthermore, the entire 710 corridor improvement project must from inception result in a reduction in criteria pollutants (particulate matter, ozone, nitrogen dioxide, and carbon monoxide) in the corridor and rail and port communities, as compared to 2002 baseline values according to the SCAQMD, State standards, or National Ambient Air Quality Standards, whichever are lower, and that reduction must be maintained. The lowering of emissions shall include those from the ports of Long Beach and Los Angeles. No construction project on the mainline shall move forward until credible, acceptable plans for achieving this reduction are received and approved by the OPC and Tier 2 CAC.

3. Prior to the initiation of the environmental review process, all Tier 1 Community Advisory Committees (CACs) must have formally endorsed (signed off on) the freeway improvement design concept.

4. Prior to adopting a preferred alternative, the OPC must conduct a study of potential goods movement alternatives (such as the use of maglev system for freight movement) as an alternative to increasing the capacity of the I-710 Freeway; this study must include a cost benefit analysis.

5. A study of the impact of construction on air quality, traffic, congestion, noise and impact on surrounding communities must be conducted, and if construction does go forward, specific mitigation plans must be developed and put into effect during the construction process to minimize and mitigate the impact of said construction of the surrounding communities.

6. Major infrastructure improvements must be conditioned on achieving a net decrease in noise impacts upon the affected communities.

IV. Health

SYNOPSIS OF FINDINGS:

Air quality is the number one public health issue. Poor air quality has significant negative impacts on public, economic, environmental and community health in the corridor. Other parts of the environment, such as water quality, are also negatively impacted by goods movement.

Particulates and other pollutants from diesel truck traffic in the I-710 Corridor and the ports of Long Beach and Los Angeles are our communities' primary air-quality-related health concern. Ports and all associated transportation such as trucks, trains, ships, and yard equipment are the major sources of pollution along the I-710 corridor. Cars continue to be a source of air quality and health concerns in the corridor as well, but the continuing increase in port activities has focused corridor community attention on cargo movement-related emissions (ships, trucks, trains, and yard equipment). Noise is also a significant health issue, but because this issue has additional ramifications, it is treated in depth in a separate section of this report.

RECOMMENDED STRATEGIES

1. **Develop an action plan to improve air quality in the corridor, including the following steps:**
   a. Establishing a baseline of current levels of pollution from each contributing source using the best available technology.
   b. Identify the level of air quality impacts from increasing trucking, rail and shipping.
   c. Determine the approximate costs of health care that can be traced to the differential levels of air pollution to be encountered by corridor community members as a result of the construction effort, if it goes forward as envisioned.
   d. Study the direct and indirect health and other economic costs on communities and the region caused by global trade and its associated pollution impacts.

2. **Implement a corridor level action plan to improve community air quality**
   a. Use enforcement, truck inspections and incentives to control emissions.
   b. Require air quality improvements in port operation as a condition of project approval.

c. Encourage the development and expansion of fleet modernization clean air programs.
d. Levy fees on containers to fund environmental improvements and community programs to address hidden costs attributable to goods movement impacts including:
   - Health care
   - Alternative fuels
   - Improvements/construction of I-710 infrastructure
   - Beautification of the corridor
e. Develop infrastructure that quantifies emission reductions:
   - Permanent monitoring stations to measure emissions levels in the corridor
f. Develop and implement improved air quality monitoring techniques.

3. Implement local alternative fuels/electrification and/or hydrogen policies and programs to reduce diesel emissions.

a. Make the use of alternative fuels a priority.
b. Discourage use of out-of-state fuel.
c. All trucks, regardless of origin, must be subject to local, state and federal standards
d. Require all trucks using the truck lanes on the I-710 to use alternative fuels as defined above, or pollution controls which achieve equal or better results.
e. Require all railroad locomotives servicing the two ports, or any rail yards connected with port container traffic, to use alternative fuels as defined above, or pollution controls which achieve equal or better results.
f. Require the Alameda Corridor Authority to prepare a plan to electrify all locomotives involved in its operations.

4. Pursue opportunities for incremental improvements

a. Retrofit schools, homes and parks to increase protection from noise and pollution.
b. Identify location and develop facility for one-stop truck inspection.
c. Provide incentives for businesses to accept off-peak deliveries.
d. Create programs to assist truck owners with engine/equipment upgrades and retrofits.
e. Restrict Port-generated traffic onto I-710 until improved fuels programs or other pollution emissions mitigation programs are implemented.
f. Provide landscaping, specifically including tree planting, to improve air quality.

5. Implement Port-specific strategies

a. Require ports to develop plans to electrify other terminal operations as a priority.
b. Require all rubber tired gantry cranes to be electrified.
c. Require all ships docking in the Ports of Los Angeles and Long Beach to shut down all diesel engines and use shore electric power.
d. Require the ports to expedite development of effective pollution controls for ships.
e. Make mandatory the proposal of CARB to require that ships entering the coastal waters of California switch to low sulfur diesel fuel. Require the ports to provide financial subsidy if necessary to implement this requirement.
f. Include trucks, trains and rail yards, marine vessels, and port equipment in clean air initiatives.
g. Require all terminal equipment at the ports to operate on alternative fuel as defined by CARB. This includes Liquid Petroleum Gas, Compressed Natural Gas, or Liquid Natural Gas. As an alternative, require all engines to be equipped with pollution control technology, which achieves equal or less emissions.
h. Establish a fund that shippers must pay into, that provides rebates to those who adopt the use of clean air engines for vehicles. Ensure that this program accomplishes the goals of decreasing pollution rather than a pay-to-pollute program.

POLICY CONSIDERATIONS

The first consideration for approval of any improvements within the I-710 corridor must be the project's ability to reduce air quality impacts. Air quality in the corridor must be better at the time of construction than it is today. Therefore, these steps to reduce air pollution must be taken before construction can begin on the "mainline" project.

V. Jobs and Economic Development

SYNOPSIS OF FINDINGS

The central location of the Gateway communities and proximity to ports, waterfronts, airports, downtown, Orange County and the Inland Empire has been undercapitalized. The ports provide economic benefit but statistics do not exist that can track these benefits back to specific communities. Therefore, communities are not convinced of the specific level of benefit provided by the ports in comparison to the cost caused by port and freight operation. In recent years, the area has been in transition from high-quality, high-paying manufacturing and aerospace jobs to lower-pay manufacturing and logistics jobs. Improvement of air quality and the environment are essential for the area to take advantage of and capitalize on the area's assets. In addition, an investment in education is necessary to continue to diversify the economy and provide economic opportunity for residents. Finally, there is some measure of competition among the ports, resulting in lack of cooperative planning at the regional, state, national and international levels.

RECOMMENDED STRATEGIES

1. **Position the I-710 corridor and Gateway communities as leaders in the post-oil economy**
   a. Develop and sponsor job training programs for alternative fuel vehicle retrofit and manufacturing, which will fit into a retrofit program implemented by the lead agency.
   b. Re-think and re-organize alternative/non-oil methods and operations for goods movement throughout the region.
   c. Conduct a feasibility study for an alternative transportation system such as Maglev.

2. **Create a community environment that attracts and retains businesses and residents who can support a new gateway cities economy**
   a. Improve health, air quality and infrastructure.
   b. Provide economic incentives for industries, and especially environmentally friendly industries, which offer the greatest multiplier effect and improve the region's quality of life.
   c. Use the experience of other waterfront cities, such as Boston, New York, London, and Melbourne, as models for redevelopment.

3. **Enable the I-710 corridor and Gateway communities to become more proactive in today's economy**

a. Conduct a cost/benefit analysis of the international goods movement industry to determine the economic impact of international trade on the corridor communities.
b. Reduce the communities' over-reliance on jobs that damage the quality of life by supporting the development of other, more community-friendly industries.
c. Create or support regional mechanisms for sustainable economic development.

4. **Institute corridor-wide programs and partnerships to equip area residents with the skills needed to move into higher-paying jobs in this new economy**
   a. Develop and promote education, training and internship opportunities for youth and young adults.
   b. Build on existing adult education and vocational training programs.
   c. Establish strategic partnerships between corridor cities, the Gateway Cities COG, community colleges, regional occupational programs, and local business.
   d. Dedicate an incremental percentage of container fees to partially fund job training and development programs.
   e. Provide training to allow employees to transition from traditional truck, port and train jobs to alternative transportation systems such as maglev.

5. **While promoting the importance of all business, recognize small business, as an economic driver, and foster its growth within the communities**
   a. Encourage land use and economic policies that support small business development.
   b. Promote fee structures and amenities that attract and encourage small business growth.

6. **Consistent with current law, advocate policies at the national, state, regional and local levels to require businesses that benefit from any potential I-710 improvements to pay living wages.** *(Note: Consensus was not reached on this specific recommendation. Dissent included, "the concept of living wages is unrealistic and unenforceable.")*

POLICY CONSIDERATIONS

The twin ports of the San Pedro Bay generate significant economic benefits to the Southern California region and the nation as a whole by facilitating the rapid growth in international trade. However, the cost associated with the movement of goods, whether through the ports or the region's arterial highway, freeway or rail corridors, is primarily

borne by local communities. The cities adjacent to the ports as well as the cities bordering the major transportation corridors, especially the I-710, experience increased levels of pollution. These external costs have reduced the attractiveness and livability of these communities. To address this imbalance, local residents and businesses must be net beneficiaries of the continued growth in international trade. Not only must programs be earmarked for local residents and businesses, but companies who locate in corridor communities must also be encouraged to hire locally. In addition, major construction projects should be structured to incorporate effective programs to provide local residents with jobs. At the same time, there is a clear obligation to implement mitigation measures to reduce the adverse effects associated with goods movement.

VI. Safety

SYNOPSIS OF FINDINGS

The I-710 corridor is one of the most unsafe freeways in the State. Increasing truck traffic, conflicts between cars and trucks, aging infrastructure and outdated design are all contributing causes to accidents in and around the freeway. In addition, the high concentration of older trucks is a significant contributing factor to the frequency of disabled big rigs, which pose a significant safety hazard. Truck intrusion into nearby communities and neighborhoods also negatively impacts street safety in these areas. While the Alameda Corridor grade separations have improved the safety of street crossings within the corridor, other freight and rail operations continue to be a source of concern for the communities. Furthermore, the current sub-standard design features of the I-710 significantly contribute to the traffic safety problems associated with the corridor, and demand safety design upgrades and improvements.

RECOMMENDED STRATEGIES

1. **Continue support and implementation of safety programs**
   a. Support the Gateway Cities Council of Governments (COG) Safety Initiatives.
   b. Support implementation of MTA Big Rig Tow program.
   c. Encourage goods movement industry to revise its rate structure in order to support truck upgrades.

2. **Increase enforcement of traffic and vehicle safety laws and regulations**
   a. Establish permanent truck inspection station(s).
   b. Monitor vehicle speeds and enforce speed limits.
   c. Support safe driving of trucks through added enforcement.
   d. Support safe driving of vehicles in the presence of trucks through added enforcement.
   e. Enforce a truck certification program for all trucks

3. **Increase public and trucker education on safety and neighborhood issues**
   a. Utilize CHP materials to increase public awareness.
   b. Educate drivers about truck stopping speed and distances and truck driver blind spots.

4. **Implement infrastructure improvements**

a. Ensure that median barriers are in place along the full length of the freeway, and that they are high enough to increase protection, minimize traffic delays created by glare and drivers slowing to view accidents.
b. Improve lighting while fully mitigating light pollution from all sources including port and rail yards.
c. Improve existing informational signage.
d. Link signage to Intelligent Transportation Systems (ITS).
e. Re-surface the I-710 Freeway, making no assumptions that doing so should necessarily add capacity.
    i. If there is a major corridor improvement on the mainline, provide separate lanes for trucks and vehicles.

POLICY CONSIDERATIONS

Any improvements to the I-710 corridor must resolve the inherent conflicts between automobiles and trucks. Just as the Alameda Corridor helped reduce the conflicts between trains and automobiles, improvements to the I-710 corridor should lead to a safe highway infrastructure that resolves the truck/auto conflict, provides the opportunity to remove unsafe vehicles from the road, and creates a more efficient transportation corridor based on good information and safer geometric design features using the most current highway design standards, while minimizing and mitigating the impacts to the surrounding neighborhoods.

VII. Noise

SYNOPSIS OF FINDINGS

Excessive noise is a serious concern in the corridor. Noise has been shown to impact learning ability, skills development and quality of life. While not all noise can be eliminated, noise can be controlled through design and operational strategies, sound walls and retrofit of homes, schools and equipment. Noise must be controlled and we must find the means to do so.

RECOMMENDED STRATEGIES

1. **Provide appropriate and effective sound walls to reduce noise impacts to neighborhoods and schools adjacent to the freeway**
   a. Make sound walls along the freeway consistent in appearance, attractive and well designed. Plant native vines on walls to discourage graffiti.
   b. Ensure that sound walls and noise abatement treatments are designed, budgeted and installed before construction begins, and take into account steps necessary to shield residents from the noise of construction itself.
   c. Ensure that additional sound buffers, such as sound walls and landscaping are installed where double decking occurs, to ensure no increase in overall levels in residential areas.

2. **Implement noise mitigation programs**
   a. Retrofit homes and schools near the freeway, freight routes and rail yards with double-paned glass and air conditioning or other sustainable methods for reducing noise such as landscaping and window shades.
   b. Trucks using the corridor must utilize the latest noise reduction technology, including retrofitting of old trucks to decrease noise.
   c. Implement train noise mitigation for communities near rail yards and rail ways.
   d. Aggressively enforce train switching and truck engine brake laws.
   e. Ensure noise mitigation during construction, including mitigation related to truck diversion on all detour routes and “hot spots” in the corridor.
   f. Design the freeway system so that there is a lower ambient noise level in communities.
   g. Choose road surfaces that result in lower noise levels. Noise levels associated with any improvements must not exceed CNELs in local land use plans.

3. **Conduct a study to assess how truck traffic from extended gate hours for trucks and 24/7 port operations will impact communities, and assess what mitigations may be appropriate.**
   a. Designate special truck routes through communities, and create them, if needed, utilizing designs that will result in lower noise and pollution levels in residential neighborhoods.
   b. Adopt policies and enforcement mechanisms to reduce and prevent truck idling on city streets, and encourage new technologies in this endeavor.
   c. Consider a mini-truck stop in designated areas to reduce and eliminate truck idling on city streets.

POLICY CONSIDERATIONS

Noise issues go beyond simply building more soundwalls. A comprehensive analysis of noise along the corridor must lead to a plan that recognizes the heath impacts to our communities and seeks to resolve those impacts by providing appropriate relief. Future improvements must consider noise as a primary public health issue and find ways to mitigate those impacts.

VIII. Congestion and Mobility

SYNOPSIS OF FINDINGS

Congestion is a significant quality of life issue for area residents and businesses. The major purpose of congestion relief must be to improve the quality of life and economic vitality of the corridor rather than simply to accommodate ports growth. Although the port's growth is a major contributing factor to the increased traffic on the I-710 corridor, the ambient background growth must be considered and mitigated as well. The current corridor capacity is not adequate even for the existing demands in the area. It is necessary to identify multi-modal capacity enhancements along the I-710 corridor and the region to address congestion and mobility. Alternative transportation has been an underdeveloped asset in the corridor, especially mass transportation, bicycle and pedestrian options. Since many corridor and freeway improvements may require construction, we must recognize potential negative impacts from this construction and aggressively plan ahead to deal with them. While expanded hours for the ports can decrease congestion during daytime hours, this policy can also increase nighttime impacts on neighborhoods. Measures are needed to anticipate, plan for and mitigate these impacts.

RECOMMENDED STRATEGIES

1. **Maximize use of existing infrastructure**
    a. Synchronize signals along major arterials.
    b. Consider extended gate hours for trucks and 24/7 port operations if ways can be found to ensure that there will be no impact on adjacent residential areas.
    c. Encourage full utilization of the Alameda Rail Corridor and vigorously pursue additional use possibilities.
    d. Support policies that support near dock facilities.
    e. Regulate port- and rail-generated traffic onto I-710 based on I-710 capacity.
    f. Encourage use of mass transit.
    g. Encourage alternative business hours by employers to distribute commuter traffic to non-peak hours.
    h. Encourage alternative business hours to accommodate trucks during off peak commuter hours, so long as the impact to the community is minimal.

2. **Transit**
    a. Create links to other forms of public transportation.

b. Close gaps in bus service.
c. Expand light rail system.
d. Make use of alternative transportation such as maglev for port use and people moving.
e. Provide incentives for use of mass transit, including rideshare and other modes.

3. Provide a comprehensive bicycle and pedestrian network that provide connectivity throughout the area

a. Utilize existing bike and pedestrian trails and provide new ones along the Los Angeles River Corridor.
b. Establish east-west connections across the freeway to unite communities and provide access to the Los Angeles River bike trail.
c. Provide for bike lanes and sidewalks in all aspects of arterial improvements to the I-710 corridor.

4. Develop a consistently implemented plan with cities and residents to mitigate construction impacts and maintain access

a. Examine truck destinations to create alternate routes.
b. Mitigate impacts in all areas that are in proximity to local schools.
c. Restrict the construction hours to off-peak hours, and maximize the nighttime construction activities with full consideration for its noise and light impacts.
d. Support legislation (such as original language contained in AB2041) to encourage extended gate hours and to help mitigate truck traffic.

5. Support cooperative planning among all ports along the West Coast

a. Address impacts and develop consistent fee structures and policies with regard to containers.
b. Expand cooperative port efforts beyond Los Angeles/Long Beach to West Coast, national and international policies. Support a common fee structure among ports so that there is not an incentive to move freight operations based on fees paid.
c. Support legislation (such as in the original AB 2043) to develop and maintain a long-range plan for West Coast port planning and general transportation and distribution. Future port planning must take into account roadway and rail capacity not just terminal capacity.

6. Create additional options to address long-term capacity needs.

a. Consider long-term impacts of elevated roadways on the local economy and environment.

b. Study the use of underground truckways to relieve congestion of surface traffic when surface truckways approach "design capacity".

7. Address and Manage Impact of National Goods Movement Trends on Local Facilities.

a. Set a goal to redirect a portion of imports destined outside Southern California to other West Coast ports.

POLICY CONSIDERATIONS

The goal of congestion and mobility relief is to improve the movement of goods and people significantly reducing health impacts and enhancing quality of life. The strategies suggest an approach that provides multiple options for personal mobility – auto, pedestrian, bike and transit – within the corridor. Likewise, the outcome for goods movement must be a comprehensive approach towards a regional network that reduces bottlenecks in all segments – ship, truck, and rail – but is not primarily to promote port growth. The current conditions along the corridor are simply not acceptable.

IX. Community Enhancements

SYNOPSIS OF FINDINGS

The I-710 corridor is more than just a place for trucks to pass through on their way to their final destination. It is the location of our homes, businesses, schools, parks, and lives. A significant consideration for all projects is how they enhance and upgrade the natural and built environment along the corridor. A revitalized I-710 must be the catalyst that improves the region's quality of life and makes the area an even more desirable place to live, work, and play.

RECOMMENDED STRATEGIES

1. **Preserve existing parks, opens space and natural areas**
   a. The design must accommodate additional planned park, open space and wetlands projects in the corridor.
   b. All mitigation funding for this project related to the impacts on open space, parklands or habitat will be used to implement Los Angeles River and tributary, or other open space, habitat restoration, recreational and educational opportunities within the corridor.
   c. There must be no net decrease in the amount of permeable surface as a result of the I-710 corridor project.
   d. Design ramp abandonment and other corridor-related infrastructure improvements to make maximum use of these areas for community open space and enhancement projects.
   e. There must be no negative impacts to the Los Angeles River, Compton Creek or other open channels in the corridor as a result of this project.
   f. To the maximum extent possible, landscaping materials used for this project should be local native plants.

2. **Develop and implement community enhancement projects**
   a. Coordinate with local city redevelopment departments to identify priority enhancement areas.
   b. Utilize input from CAC to develop community enhancement priorities.
   c. Emphasize landscaping and aesthetic improvements to major arterial routes within the corridor.

3. **Provide programs to minimize construction impacts**
   a. Establish construction staging areas in locations with the least amount of impact on local circulation.

b. Establish a community forum to identify and rectify impacts during construction.

4. Develop and implement a plan for arterial streetscapes

a. Landscape medians, using native plants and recycled water where possible.
b. Utilize signage, which identifies communities and connections to local rivers, i.e., LA, Compton Creek, Rio Hondo, bikeways, parks and historical landmarks.

5. Mitigate light and glare in surrounding communities

POLICY CONSIDERATIONS

As the import/export industry continues to grow and generate traffic in the ports, the corridor communities continue to be burdened without any significant gain. The inherent potential of these communities cannot be fully realized until their perception as unattractive and economically challenged communities is changed. Plans for future improvements to the I-710 are not intended to solely address congestion and mobility problems but to enhance local communities along the corridor. Major infrastructure improvements must also be conditioned on conclusion of satisfactory agreements with the neighboring communities to fully mitigate negative aesthetic impacts and to mitigate the impacts if any increased light and glare.

X. Design Concepts

SYNOPSIS OF FINDINGS

The Committee recognizes that something must be done to address the current congestion and design of the I-710 freeway. The high number of trucks on the freeway uses up capacity and the mix of cars and trucks poses a serious safety concern. Measures must be taken to separate cars from trucks. In addition, the design of the freeway is outdated and contributes to the safety and congestion problem. A new design concept for I-710 and/or alternative transportation modes for vehicles and goods movement is needed that responds to the specific design recommendations developed by the Tier 1 CACs to minimize or limit take of homes within their communities along I-710. The Committee further recognizes that certain aspects of the design concepts, particularly for designated on-ramps, may be appropriate for implementation prior to addressing the "mainline" issues. The Committee further recognizes that in addition to addressing air quality goals, prior to implementation of any mainline major infrastructure improvements there must be a definitive cost benefit analysis and environmental review to determine if there are alternative methods for addressing the capacity and safety deficiencies of the I-710 corridor. Therefore, these recommended strategies are premised on meeting those conditions.

RECOMMENDED STRATEGIES

1. **Support capacity enhancement improvements for the I-710 Freeway upon meeting the conditions recommended in this report.**
    a. Actively pursue and finalize the cost benefit and environmental studies required in the above synopsis of findings.
    b. Advocate the inclusion of the I-710 corridor improvements for special earmark consideration in the federal transportation finance bills. To the extent possible, it is the committee's desire that truck-related improvements and mitigations be financed by truck and port fees.
    c. Actively pursue and develop creative funding alternatives to finance the design and capacity enhancement improvements for the I-710 corridor.

2. **If economic and environmental studies show that expansion of the freeway is necessary, develop new transportation infrastructure for I-710 that separates cars from trucks.**
    a. Add lanes for trucks that are separate from the I-710 freeway lanes.

b. Build truck ramps that lead directly from I-710 to the railroad yards to take truck traffic out of neighborhoods and off of local streets.
c. Improve the Atlantic and Bandini intersection in the City of Vernon.
d. Improve the Atlantic and Bandini interchange to the south (Garfield to I-5 South).

3. If economic and environmental studies show that expansion of the freeway is necessary, locate the new truck lanes in such a way as to minimize community impacts

a. Utilize property between the existing freeway and the Los Angeles River to minimize taking of residences, local businesses and parks.
b. Truck lanes should be located in those lanes that are at the greatest distance from homes, parks and schools to limit noise and emissions impacts on the community.
c. Keep trucks at or below grade to reduce potential for noise and visual impacts.

4. Redesign unsafe and congested interchanges on I-710

a. Implement diamond interchange modifications as recommended by Tier 1 communities.
b. Maintain and improve local access to I-710 for residents and businesses.
c. Widen bridges that cross and parallel the I-710 to provide sufficient space for cars, bicyclists, and pedestrians.

5. Consider the future in implementing new I-710 design

a. Provide for future mobility in the long run by preserving options to use advanced technologies for moving goods as these are developed.
b. Use utility right-of-way to minimize community impacts.
c. Future port planning must take into account roadway and rail capacity, not just terminal capacity.

6. If economic and environmental studies show that expansion of the freeway is necessary, upgrade of the existing freeway must:

a. Ensure that sufficient capacity is provided for the general public by making improvements to the existing freeway (mainline) as presented by the Tier 1 design concepts.
b. The mainline portion of I-710 will be upgraded to modern design standards.
c. Continue working with those communities north of the rail yards to finalize design concepts in that area.

POLICY CONSIDERATIONS

We cannot entirely build our way out of congestion. Therefore, any freeway improvements project must be accompanied by other policies and programs such as those described in the congestion and mobility strategies. At the same time, the current status of the I-710 is not acceptable to the communities that depend on it and are affected by it. The hybrid design does a credible job of showing that maximum build out may be accommodated while incorporating community concerns about land use. However, further study is required to determine if there are other feasible alternatives that would substantively address the local communities' concerns. Final decisions on project configuration can only be made subsequent to the cost benefit and environmental studies required in the synopsis of findings. These improvements cannot be constructed in isolation from all of the other recommendations such as public health, community enhancement, and noise abatement. The I-710 design must take into account the safety and quality of life of the communities located next to the freeway, including provisions for greenbelts and open space.

XI. Environmental Justice

SYNOPSIS OF FINDINGS

In the fifty years since the freeway was first built, demographics have changed within the corridor. Today the corridor is home to low-income populations and minority groups, including African American, Asian, Latino, Pacific Islander and Native American communities. For many years, these communities have shouldered an unfair burden in health, economic, and quality of life issues in comparison with residents in other parts of the region. While the I-710 freeway is a critical factor in the region's economy, the localized negative impacts resulting from past transportation projects have more than offset their benefits in the corridor communities. Freeways have dissected some communities, and the operations of the logistics industry have compounded these impacts.

RECOMMENDED STRATEGIES

1. **Include the corridor communities in the planning process in a meaningful way, including provision of appropriate language translation.**
2. **Ensure that impacts do not disproportionately fall on low-income people or people of color.**
3. **Ensure that the benefits from the projects flow to the corridor communities.**

POLICY CONSIDERATIONS

The requirement of the environmental justice is to provide a mechanism for the meaningful involvement of all people in the transportation decision-making process and to ensure that the low-income and minority communities receive equitable distribution of the benefits from transportation activities without suffering disproportionate adverse impacts. In order to ensure equitable outcomes, future I-710 corridor projects must include "implementable" environmental justice policies and procedures that are developed by the locally affected communities. The communities' expectation is that transportation projects in their communities will meet modern standards of safety, design and aesthetics and that all negative environmental impacts will be fully mitigated. The mitigations must be, at a minimum, determined by the Tier 1 communities and other communities which might be impacted by negative environmental impacts.

XII. Organization and Process

SYNOPSIS OF FINDINGS

To ensure that the work of the Tier 2 Committee is carried forward as set forth in this document, a task force of representatives from the Tier 2 CAC, the OPC and the TAC should be established to plan and oversee the implementation of the conditions and recommendations of the Tier 2 CAC.

RECOMMENDED STRATEGIES

1. **This Tier 2 Report (Major Opportunity/Strategy Recommendations and Conditions) will be formally "agendized" and presented to the Oversight Policy Committee when it convenes in September 2004 (or as soon as possible thereafter) for its consideration and decision. All Tier 2 members will be invited to the OPC meeting, and the presentation of the Tier 2 report will be delivered by a representative group of Tier 2 spokespersons.**
2. **Following the OPC's meeting, there will be a follow-up meeting(s) of the Tier 2 Committee to discuss actions taken by the OPC.**
3. **Prior to the beginning of any formal EIR for the I-710 Major Corridor Study, Metro (MTA) and the Gateway Cities COG will work with the communities, appropriate agencies, organizations and community groups in developing a collaborative process for community participation in the environmental review process. This process will continue to work collaboratively throughout the EIR process.**

Appendix A

Strategies Summary Matrix

GUIDE TO INTERPRETING THE STRATEGIES SUMMARY MATRIX

The Strategies Summary Matrix lists the strategies recommended by the Tier 1 and Tier 2 Community Advisory Committees. The purpose of the Summary Matrix is to synopsize these strategies and to track the source of the recommended strategies.

The strategies are organized by the themes developed by the Tier 2 CAC and are referenced as follows:

H – Health
J - Jobs and Economic Development
S -- Safety
N -- Noise
M -- Congestion and Mobility
E -- Community Enhancements
D -- Design Concepts
EJ -- Environmental Justice
P -- Organization and Process

Guide to ID# Column Interpretation:

e.g. H1-a:

H = Located in the Health Section of the Tier 2 Report
1 = Strategy #1 in this Section
a = Designation of the specific recommendation under this Strategy

Source Column

Identifies the source of the recommendation:

- Tier 2
- Tier 1 & Tier 2
- Tier 1 only (note: These appear in ***italics*** and are strategies that were recommended by many Tier 1 communities, but not specifically called out in the Tier 2 Committee's final report.)

Programs/Policies

Strategies that relate to programmatic and policy recommendations

MCS Transportation Actions

Recommended Major Corridor Study (MCS) construction or mitigation activities to complement improvements to the I-710 mainline.

I-710 Design Concepts

Infrastructure improvement recommendations on the I-710 mainline interchanges.

					TYPE		
ID#	**Strategy Type**	**Recommendation**	**Description**	**Source**	**I. Programs/Policies**	**II. MCS Transportation Actions**	**III. I-710 Design Concepts**
			HEALTH				
H1-a	**Air Quality Improvements**	AQ Improvement Action Plan	Establish a baseline of current levels of pollution.	Tier 1 & Tier 2	X		
H1-b			Identify level of air quality impacts from increasing truck, rail and shipping.	Tier 1 & Tier 2	X		
H1-c			Determine costs of health care that can be traced to pollution encountered by corridor community members as a result of construction.	Tier 2	X		
H1-d		Global Trade Expansion: Impact Assessment	Perform studies to determine direct and indirect health and other economic costs on corridor communities and region.	Tier 2	X		
			Determine how other ports are addressing health and air quality issues.	*Tier 1*	X		
H2-a		Truck Inspection	Use enforcement and increase inspections to control emissions.	Tier 1 & Tier 2	X		
H2-b		Port Emissions Reduction	Condition project approval on air quality improvements in Port operations	Tier 1 & Tier 2	X		
H2-c			Encourage development/expansion of fleet modernization clean air programs	Tier 2	X		
H2-d		Container fees	Impose container fees to generate revenue to enhance corridor communities and address impacts.	Tier 1 & Tier 2	X		
H2-e		Quantify Emissions	Install permanent monitoring stations to measure emissions levels.	Tier 1 & Tier 2	X		
H2-f			Develop and implement improved air quality monitoring techniques.		X		
H3-a	**Diesel Emissions Reduction**	Alternative Fuels	Support policies that encourage use of alternative fuels.	Tier 1 & Tier 2	X		
H3-b			Discourage use of out-of-state fuel.	Tier 1 & Tier 2	X		
H3-c			Subject all trucks to local, state and federal standards.	Tier 1 & Tier 2	X		
H3-d			Require trucks using I-710 to use alternative fuels or equivalent pollution controls.		X		
H3-e			Require railroad locomotives servicing the two ports to use alternative fuels.	Tier 1 & Tier 2	X		
H3-f			Require the Alameda Corridor Authority to prepare a plan to electrify locomotives involved in its operations.	Tier 1 & Tier 2	X		
H4-a	**Environmental Improvements**	Emissions Reduction and Mitigation	Retrofit schools, homes and parks to increase protection from noise and pollution.	Tier 1 &Tier 2	X		
H4-b			Identify location and develop facility for one-stop truck inspection.	Tier 1 & Tier 2		X	
H4-c			Provide incentives for business to accept off-peak deliveries.	Tier 1 & Tier 2	X		
H4-d		Truck emissions reduction programs	Create programs to assist truck owners with engine/equipment upgrades.	Tier 1 & Tier 2	X		
H4-e			Restrict Port generated traffic on I-710 until emission mitigation is in place.	Tier 1 & Tier 2	X		
H4-f			Provide landscaping to improve air quality.	Tier 1 & Tier 2	X		
H5-a	**Port Air Quality**	Alternative Fuels	Require plans for terminal operation electrification	Tier 2	X		

Guide to ID# Column Interpretation
e.g. H1-a:
H = Located in the Health Section of the Tier 2 Report
1 = Strategy #1 in this Section
a = Designation of the specific recommendation under this Strategy

ID#	Strategy Type	Recommendation	Description	Source	I. Programs/Policies	II. MCS Transportation Actions	III. I-710 Design Concepts
H5-b			Require electrification of port gantry cranes.	Tier 2	X		
H5-c		Ship Operations	Require ships to shut down diesel engines and use shore electric power.	Tier 2	X		
H5-d			Require ports to expedite development of pollution control for ships.	Tier 2	X		
H5-e			Make low sulfur diesel fuel use mandatory.	Tier 2	X		
H5-f		Emissions Control	Include trucks, trains, and rail yards, marine vessels and port equipment in clean air initiative.	Tier 2	X		
H5-g			Require terminal equipment emissions controls.	Tier 2	X		
H5-h		Funding	Establish shipper-funded emissions-lowering incentives.	Tier 2	X		
JOBS AND ECONOMIC DEVELOPMENT							
J1-a	**Local Economic Development**	Create New Corridor Economy	Provide job training programs for alternative fuel retrofit and manufacturing.	Tier 2	X		
J1-b			Reorganize and re-think alternative methods and operations for goods movement through the corridor that are not reliant on oil.	Tier 2	X		
J1-c			Conduct a feasibility study for alternative transportation system.	Tier 2	X		
J2-a		Support New Corridor Economy	Improve health, air quality and infrastructure to retain businesses and residents.	Tier 2	X		
J2-b			Provide economic incentives for industries which contribute to improving the region's quality of life.	Tier 1 & Tier 2	X		
			Create local jobs to avoid commuting out of the corridor for better paying jobs.	*Tier 1*	X		
J2-c			Use experiences of other waterfront cities as models for redevelopment.	Tier 1 & Tier 2	X		
J3-a			Conduct a cost benefit/analysis of the international goods movement industry to determine impact on corridor communities.	Tier 2	X		
J3-b	**Job Development**	Industry Development	Support more community-friendly industries to reduce communities' over-reliance on jobs that damage quality of life.	Tier 2	X		
J3-c			Create or support regional mechanisms for sustainable economic development.	Tier 2	X		
J4-a	**Job Training**	Education	Develop and promote education, training and internships opportunities for youth and young adults.	Tier 1 & Tier 2	X		
J4-b			Build on existing adult education and vocational training programs.	Tier 1 & Tier 2	X		
J4-c			Establish strategic partnerships between corridor cities, Gateway COG, education and local business.	Tier 2	X		
J4-d		Funding	Dedicate an incremental percentage of container fees to fund job training/development programs.	Tier 1 & Tier 2	X		
J4-e			Provide training to transition employees from traditional logistics jobs to jobs in alternative transportation systems.	Tier 2	X		
J5-a	**Small Business Development**		Encourage land use and economic policies that support small business development.	Tier 2	X		
J5-b			Promote fee structures and amenities that attract and encourage small business growth.	Tier 2	X		
J6			Encourage policies that promote "living wages" for area logistics businesses.	Tier 2	X		

Guide to ID# Column Interpretation
e.g. H1-a:
H = Located in the Health Section of the Tier 2 Report
1 = Strategy #1 in this Section
a = Designation of the specific recommendation under this Strategy

ID#	Strategy Type	Recommendation	Description	Source	I. Programs/Policies	II. MCS Transportation Actions	III. I-710 Design Concepts
SAFETY							
S1-a	**Safety Programs**	Advocacy	Support the Gateway Cities Council of Governments (COG) Safety Initiatives.	Tier 2	X		
S1-b		Road Assistance	Support MTA "Big Rig Tow" program.	Tier 1 & Tier 2	X		
S1-c		Truck Upgrades	Encourage goods movement industry to revise its rate structure in order to support truck upgrades.	Tier 2	X		
S2-a	**Enforcement**	Truck Inspection	Establish permanent truck inspection station(s).	Tier 1 & Tier 2	X		
S2-b		Speed Monitoring	Monitor vehicle speeds and enforce speed limits.	Tier 1 & Tier 2	X		
S2-c		Increased Enforcement	Support safe driving of trucks through added enforcement.	Tier 1 & Tier 2	X		
S2-d			Support safe driving of vehicles in the presence of trucks through added enforcement.	Tier 1 & Tier 2	X		
S2-e		Truck Certification	Enforce a truck certification program for all trucks.	Tier 2	X		
			Create truck driver training and licensing programs.	*Tier 1*	X		
S3-a	**Education**	Public/Trucker Education Campaign	Build on existing CHP campaign to increase public awareness.	Tier 2	X		
S3-b			Educate drivers about truck stopping speed and distance and truck driver blind spots.	Tier 1 & Tier 2	X		
S4-a	**Infrastructure Improvements**	Median Barriers	Provide median barriers along the full length of the I-710 freeway.	Tier 1 & Tier 2		X	
S4-b		Lighting	Improve lighting while fully mitigating light pollution from all sources.	Tier 1 & Tier 2	X		
S4-c		Signage	Improve existing informational signage.	Tier 1 &Tier 2	X		
S4-d		Technology	Link signage to Intelligent Transportation Systems (ITS)	Tier 2	X		
			Utilize computerized message boards to post traffic alerts.	*Tier 1*	X		
S4-e		Resurfacing	Re-surface the I-710 Freeway (Provide separate lanes for trucks and vehicles if there is a major corridor improvement to the mainline)	Tier 1 & Tier 2		X	
NOISE							
N1-a	**Noise Reduction**	Sound Walls	Provide sound walls along the corridor that are consistent in appearance, attractive and well designed.	Tier 1 & Tier 2		X	
N1-b			Ensure sound walls are installed before any construction and are designed to mitigate construction impact.	Tier 2		X	
N1-c			Provide additional sound buffers where double decking occurs.	Tier 2		X	
N2-a		Noise Mitigation Programs	Retrofit homes near the freeway, freight routes and rail yards.	Tier 1 & Tier 2	X		
			Provide air conditioning and window programs for residents along the freeway edge.	*Tier 1*	X		
N2-b			Truck using the corridor must use latest noise reduction technologies.	Tier 1 & Tier 2	X		
N2-c			Provide train noise mitigation for communities near rail yards.	Tier 1 & Tier 2	X		
N2-d		Enforcement	Enforce train switching and truck engine brake laws.	Tier 2	X		
N2-e		Construction Mitigation	Ensure noise mitigation during construction.	Tier 1 & Tier 2	X		
N2-f		Design	Design the freeway system to lower ambient noise levels in communities.	Tier 2			X
N2-g			Use road surfaces that result in lower noise levels.	Tier 1 & Tier 2			X
N3-a		Alternate Routes	Designate special truck routes through communities and use designs that will result in lower noise pollution.	Tier 1 & Tier 2	X		
			Encourage use of some arterials as routes for trucks.	*Tier 1*	X		
			Encourage use of other freeways as routes for trucks.	*Tier 1*			
			Provide improved East/West access to other regional freeways.	*Tier 1*		X	

Guide to ID# Column Interpretation

e.g. H1-a:

H = Located in the Health Section of the Tier 2 Report

1 = Strategy #1 in this Section

a = Designation of the specific recommendation under this Strategy

ID#	Strategy Type	Recommendation	Description	Source	I. Programs/Policies	II. MCS Transportation Actions	III. I-710 Design Concepts
N3-b		Truck Noise Reduction	Adopt policies and enforcement mechanisms to reduce and prevent truck idling on city streets.	Tier 1 & Tier 2	X		X
			Partner with local business to allow shared parking opportunities on existing lots to eliminate truck parking on neighborhood streets.	*Tier I*			
N3-c			Consider a mini-truck stop in designated areas to reduce and eliminate truck idling on city streets.	Tier 1 & Tier 2	X		
			CONGESTION & MOBILITY				
M1-a	**Infrastructure Management**	Technology	Synchronize signals at arterials along corridor.	Tier 1 & Tier 2	X		
M1-b		Improved Port Operations	Consider extended gate hours for trucks and 24/7 port operations while minimizing residential impacts.	Tier 1 & Tier 2	X		
			Limit truck traffic hours and encourage more evening driving.	*Tier 1*	X		
M1-c		Freight Rail	Encourage full use of the Alameda Rail Corridor.	Tier 1 & Tier 2	X		
			Provide incentives to ship by rail.	*Tier 1*	X		
M1-d			Support building near dock-rail facilities.	Tier 1 & Tier 2		X	
M1-e			Regulate port- and rail-generated traffic and link to I-710 capacity.	Tier 2	X		
M1-f	**Traffic Reduction**	Demand Management	Encourage use of mass transit.	Tier 1 & Tier 2	X		
M1-g			Encourage alternative business hours to distribute commuter traffic to non-peak hours.	Tier 1 & Tier 2	X		
M1-h		Logistics Operations	Encourage alternative business hours to accommodate trucks during off-peak commuter hours.	Tier 1 & Tier 2	X		
M2-a	**Transit**	Mass Transit Improvements	Create links to other forms of public transportation.	Tier 1 & Tier 2	X		
			Create better connections between existing light rail and bus system.	*Tier 1*	X		
M2-b			Close gaps in bus service	Tier 1 & Tier 2	X		
M2-c			Expand light rail system.	Tier 1 & Tier 2		X	
			Build light rail along the I-710 to relieve auto congestion.	*Tier 1*		X	
M2-d		Alternative Transportation	Make use of alternative transportation such as maglev for port use and people moving.	Tier 1 & Tier 2	X		
M2-e		Incentives	Provide incentives for use of mass transit, including rideshare and other modes.	Tier 1 & Tier 2	X		
M3-a	**Connectivity**	Bike and ped trails	Use existing bike and pedestrian trails and provide new ones along the LA River Corridor.	Tier 2	X		
M3-b			Establish east-west connections across the freeway.	Tier 2		X	
M3-c			Provide for bike lanes and sidewalks in all aspects of arterial improvements to I-710 corridor.	Tier 2	X		
M4-a	**Construction Mitigation**		Examine truck destinations to create alternate routes.	Tier 1 & Tier 2	X		
M4-b			Mitigate all areas that are in proximity to schools.	Tier 1 & Tier 2	X		
M4-c			Restrict construction to off peak hours.	Tier 1 & Tier 2	X		
M4-d			Support legislation to encourage extended gate hours to mitigate truck traffic.	Tier 1 & Tier 2	X		
M5-a	**Port Planning**	West coast port cooperative planning	Address impacts and develop consistent fee structures and policies with regard to containers.	Tier 1 & Tier 2	X		
M5-b			Expand cooperative port efforts beyond Los Angeles/Long Beach.	Tier 1 & Tier 2	X		
M5-c			Support legislation to develop and maintain a long-range plan for West Coast port planning and general transportation and distribution.	Tier 1 & Tier 2	X		

Guide to ID# Column Interpretation

e.g. H1-a:

H = Located in the Health Section of the Tier 2 Report

1 = Strategy #1 in this Section

a = Designation of the specific recommendation under this Strategy

ID#	Strategy Type	Recommendation	Description	Source	I. Programs/Policies	II. MCS Transportation Actions	III. I-710 Design Concepts
M6-a	**Alternative Options**	Elevated Roadways	Consider long-term impacts of elevated roadways on the local economy and environment.	Tier 1 & Tier 2	X		
M6-b		Underground Roadways	Study the use of underground truckways to relieve congestion of the surface traffic when surface truckways approach "design capacity".	Tier 1 & Tier 2	X		
M7-a		Redirect Imports	Redirect a portion of imports destined outside Southern California to other West Coast ports.	Tier 1 & Tier 2	X		
COMMUNITY ENHANCEMENTS							
E1-a	**Preservation**	Parks and Open Space & Natural Areas	Accommodate additional planned park, open space and wetlands projects in corridor.	Tier 1 & Tier 2	X		
E1-b			Use open space-related mitigation funds to implement Los Angeles River and community projects.	Tier 1 & Tier 2	X		
E1-c			There must be no net decrease in the amount of permeable surface as a result of the I-710 corridor project.	Tier 1 & Tier 2	X		
E1-d		Community Open Space	Design ramp abandonment and other corridor-related infrastructure improvements to make maximum use of these areas for community open space and enhancement projects.	Tier 1 & Tier 2	X		
E1-e		Water Quality Protection	Any project should not have any negative impacts to the LA River, Compton Creek or other open channels in the corridor.	Tier 2	X		
E1-f		Native Plants	Encourage the use of native plants as landscaping materials used for this project.	Tier 2	X		
			Provide extensive landscaping along 18-mile corridor to improve community aesthetics and image.	*Tier 1*	X		
E2-a	**Community Enhancement Projects**	Agency Coordination	Coordinate with local city redevelopment departments to identify priority enhancement areas.	Tier 2	X		
E2-b		Prioritization	Develop community enhancement priorities using CAC input.	Tier 2	X		
E2-c		Landscaping	Emphasize landscaping and aesthetic improvements to major arterial routes within the corridor.	Tier 1 & Tier 2	X		
E3-a	**Mitigation**	Construction Staging	Establish construction staging areas in locations with the least amount of impact on local circulation.	Tier 1 & Tier 2	X		
E3-b		Community Consultation	Establish community forum to identify and rectify impacts during construction.	Tier 1 & Tier 2	X		
E4-a		Arterial Streetscapes	Landscape medians.	Tier 1 & Tier 2	X		
E4-b		Signage	Provide signage which identifies communities and connections to local natural areas and landmarks.	Tier 2	X		
E5		Light Mitigation	Mitigate light and glare in surrounding communities.	Tier 1 & Tier 2	X		
DESIGN CONCEPTS							
D1a	**Capacity Enhancement**	Studies/Assessment	Pursue and finalize the cost benefit and environmental studies required.	Tier 1 & Tier 2	X		X
D1-b			Finance truck related improvements through federal funds and truck and port fees.	Tier 1 & Tier 2	X		
D1-c			Actively pursue and develop creative funding alternatives to finance the design and capacity enhancement improvements for the I-710 corridor.	Tier 1 & Tier 2	X		
D2-a		Separate Trucks From Cars	Add lanes for trucks that are separate from the I-710 freeway lanes	Tier 1 & Tier 2			X
D2-b			Build truck ramps that lead directly from I-710 to the railroad yards to take truck traffic out of neighborhoods and off local streets.	Tier 1 & Tier 2			X
D2-c			Improve the Atlantic Bandidni intersection in the City of Vernon.	Tier 1 & Tier 2		X	

Guide to ID# Column Interpretation
e.g. H1-a:
H = Located in the Health Section of the Tier 2 Report
1 = Strategy #1 in this Section
a = Designation of the specific recommendation under this Strategy

ID#	Strategy Type	Recommendation	Description	Source	I. Programs/Policies	II. MCS Transportation Actions	III. I-710 Design Concepts
D2-d			Improve the Atlantic Bandidni intersection to the south (Garfield to I-5 south).	Tier 1 & Tier 2		X	
D3-a	**Minimized Impacts**	Right of Way	Utilize the property between the existing freeway and the LA River to minimize taking of residences, local businesses and parks.	Tier 1 & Tier 2	X		
D3-b			Truck lanes should be located in those lanes that are the greatest distance from homes, parks and schools to limit noise and emissions impacts on the community.	Tier 1 & Tier 2	X		
D3-c		Design and Congestion	Keep trucks at or below grade to reduce potential for noise and visual impacts.	Tier 1 & Tier 2	X		
			Make improvements to major arterials in corridor communities to relieve congestion.	*Tier 1*		X	
D4-a	**Improvements**	Interchanges and Access	Redesign unsafe and congested interchanges.	Tier 1 & Tier 2			X
D4-b			Maintain and improve local access to the freeway for residents and businesses.		X		
D4-c		Bridges	Widen bridges that cross and parallel the freeway to provide space for cars, bikes and pedestrians.			X	
D5-a		Technology	Preserve options to advanced technologies for moving goods as these are being developed.	Tier 2	X		
D5-b		Right of Way	Use utility right-of-way to minimize community impacts.	Tier 1 & Tier 2	X		
D5-c		Port Planning	Future port planning must take into account roadway and rail capacity, not just terminal capacity.	Tier 1 & Tier 2	X		
D6-a	**Capacity Enhancement Improvements**	Local Improvements	Ensure sufficient capacity is provided for the general public by making Tier 1 CAC improvements to the existing freeway.	Tier 1 & Tier 2			X
		Carpool Lanes	*Dedicate one carpool lane for vehicles with 2 or more persons on the I-710 from the 405-Long Beach.*	*Tier 1*			X
		Management	*Include transponders for greater mobility & provide incentives for use.*	*Tier 1*			X
D6-b		Design	Upgrade mainline portion of the I-710 freeway to modern design standards.	Tier 2			X
			Improve on and off ramps along the corridor.	*Tier 1*		X	
D6-c			Continue work with communities north of the rail yards to finalize design concepts in that area.	Tier 1 & Tier 2	X		
ENVIRONMENTAL JUSTICE							
EJ1	**Process**	Community Engagement	Involve corridor communities and provide appropriate language translation.	Tier 2	X		
EJ2	**Implementation**	Community Impacts	Ensure that impacts do not disproportionately fall on low-income people or people of color.	Tier 2	X		
			Impacts should be shared throughout other communities.	*Tier 1*	X		
EJ3	**Project Benefits**	Benefit Assessment	Ensure that the project benefits flow to the corridor communities.	Tier 2	X		
			Provide compensation to corridor communities that have been affected by I-710 freeway impacts.	*Tier 1*	X		
			Provide rebates to residents for use of extra water and power as a result of impacts from freeway.	*Tier 1*	X		
			Implement local employment requirements for future I-710 improvements.	*Tier 1*	X		
ORGANIZATION AND PROCESS							
P1		Presentation to OPC	Tier 2 Report will be presented to the OPC by Tier 2 representatives.	Tier 2	X		
P2		Tier 2 Follow-up	Tier 2 CAC will meet following OPC action.	Tier 2	X		

Guide to ID# Column Interpretation

Appendix B

Tier 1 CAC Community Ideas Matrices

I-710 Major Corridor Study
Tier 1 Community Advisory Committee CAC

August-04

City of Bell	
ID#	**Community Ideas**
H3-a	Our community needs to support pending legislation to address pollution.
D4-a	Improve the Florence exit and fix the cloverleaf.
D4-c	Widen bridges over the I-710 freeway.
E2-a, b	Improve sidewalk in the City.
E1-f	Implement a beautification program that includes graffiti removal and landscaping from I-91 to the I-60.
N1-a	Provide sound walls.
i	Seek opportunities to underground utilities.
N2-g	Repair potholes along the freeway.
EJ-3	City should be compensated for loss in revenue from construction impacts.
M3-a, c	Include bike trails in any potential projects.
D3-c	Improve intersection at Florence and Atlantic.
S4-d	Use Caltrans marquee to alert drivers when accidents occur.
H2-d	Assess surcharge fees on logistics industry to pay for improvements.
E3-a	Provide construction mitigation measures.
H1-d	Conduct study (funded by the ports) to determine the increased health impacts that port growth will cause.
H4-b	Increase inspection points to monitor and enforce compliance.
D6-a	Add carpool/bus lanes.
M1-b	Support 24/7 port operations.
M7-a	Encourage use of other ports.
ii	Cap port growth and rail yard expansion.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

City of Bell Gardens

ID#	Community Ideas
H4-c	Encourage trucks to use I-710 during off-peak hours. Levy higher fees/charge premium fees on companies who transport during peak hours.
ii	Build an elevated four-lane truck-dedicated express roadway, within the LA River, with minimal off-ramps to access distribution facilities with no off-ramp to Bell Gardens.
H3-a	Provide incentives for use of alternative fuels: Levy higher fees/tolls on trucks using diesel fuel and make allowances for trucks using alternative fuels. Use technology to monitor compliance.
D3-a	Relocate transmission lines between the river and I-710 freeway and use transmission right-of-way for a truck-dedicated expressway.
ii	Build a truck-dedicated roadway over the river channel that runs along the freeway.
ii	Develop additional rail distribution facilities to support out-of-state hauls to help alleviate congestion at rail yards in Commerce and Vernon.
N1-a	Sound walls should be built along the freeway in Bell Gardens to mitigate noise pollution, particularly from heavy trucks.
N1-a	Ivy should be planted on the sound walls to discourage graffiti.
H2-a	Truck inspections should be conducted regularly to ensure trucks on the road comply with safety and emission standards.
N2-d	Alameda Corridor operators should provide quieter operations for the trains.
H4-f	Create a beautification program that provides landscaping and improved aesthetics along the freeway.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

I-710 Major Corridor Study
Tier 1 Community Advisory Committee (CAC)

August-04

City of Carson	
ID#	**Community Ideas**
N3-a	Provide East West Access for trucks and autos for other regional freeways.
D2-a, b	Get trucks onto freeway more directly and quickly.
i	Examine the Terminal Island Freeway extension to 405 and its potential impacts on Carson.
ii	Use LA River for truck access.
D4-a	Provide interchange improvements.
D2-a	Consider dedicated truck lanes with transponders along I-710 next to the river and provide incentives for trucks to adopt use.
M6-b	Underground proposed improvements, if possible.
M1-d	Create a near dock facility.
M1-c	Provide incentives to ship by rail.
H4-e	Regulate truck hours.
i	Consider possibility of building below grade along Alameda Street.
i	The community does not support the Terminal Island Freeway proposal extension to Alameda Street because of the possibility of increasing the amount of truck traffic on Alameda Street traveling through Carson.
H2-b	Reduce air pollution emissions from the Port and the rail systems and support federal legislation for more stringent air quality improvements.
D1-a	Tie improvements to I-710 to air quality improvements.
H3-a	Use new clean burning fuels a soon as possible - trucks and trains.
H1-d	Perform medical studies (cancer, asthma, etc.) for the community residents along the freeway to determine the extent of the air pollution problems to these communities.
H2-d	Provide funding for the air quality impacts the residents have had to suffer from the Port and truck diesel pollution.
H4-2	Provide incentives or other financial assistance to replace older diesel truck engines.
N1-a	Provide decorative sound walls along the freeway

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

City of Carson

ID#	Community Ideas
N2-d	Alameda Corridor operators should provide quieter operations for the trains
H4-f E1-f E2-c	Create a beautification program that provides landscaping and improved aesthetics along the freeway, including trees.
EJ2	There should be equity of impacts spread among all corridor communities
M5-a	Ports should provide more efficient loading and unloading at the ports
H1-d	Look at other ports (San Diego, San Francisco, etc.) to determine how they are dealing with similar issues such as air quality and transportation
M7-a	Shift as much cargo to other ports as much as possible (Baja, Seattle, Ventura, etc.)
M1-b	24/7 Port operations (extended hours)
i	Reversible lanes
M5-b	Establish a second port in LA
H2-e	Provide a permanent, local air quality monitoring station
D2-a	Use tolls during peak hours
D2-a M6-a	Double deck the freeway starting at Port to avoid bottleneck at the Port and have it drop into a dedicated truck lane
D2-a	Add extra lanes between PCH and Willow
D5-a	Utilize TDM and TSM technologies.
H2a	Provide for truck inspection, including emissions, and increased enforcement.
N3-a	Examine other freeways in the region in addition to the I-710, provide interagency coordination and create truck routes along other freeways.
E1-a	Use the Los Angeles River green belt area.
D4-a	Provide separate truck interchanges to accommodate short-term hauling, where only limited truck access is needed.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

I-710 Major Corridor Study
Tier 1 Community Advisory Committee CAC

August-04

City of Commerce	
ID#	**Community Ideas**
H1-d	Reduce diesel emissions and other pollutants that damage air quality. The impact to our community's children is intolerable. The health of our community must become a priority! In the short-term deploy stronger enforcement; in the long-term, address the cumulative impacts that the growth in the number of trucks will have, and provide increased restrictions, insure to reduce the related increased levels of toxic emissions.
D2-c, d	Support the Bandini Alternative. It shows promise as a viable and community-supported solution. Include truck lanes on Bandini Boulevard and improving the I-5 at the Garfield interchange so trucks may go south on the I-5.
E3-a	Minimize construction impacts as much as possible, especially private property acquisition, and impacts to parks and public spaces.
M1-c	Improve public understanding through education about the purpose of the Alameda Corridor and its long-term potential as an effective and efficient transportation option.
D4-a	Explore solutions to resolve problems on both the I-5 freeway and the I-710 concurrently. It is important to recognize that these systems are dynamic and interrelated.
J3-a H1-d	Analyze the impacts on the quality of life in our community, along with possible financial impacts, of potential expanded 24/7 Port operation. Explore the local goods movement and truck route solutions that can help mitigate the impacts to our community. (This item is still subject to more community input)
N1-a	Determine the need and priority for sound walls, particularly in conjunction with other potential transportation and traffic improvements. Possible priority location could be the Bristow area, and both sides of the Washington Boulevard off-ramp.
D3-c	Oppose the proposed Slauson Avenue improvements because of the impacts in our City. The Bandini Alternative would make the Slauson improvements unnecessary.
ii	Explore the riverbed as a potential heavy-rail corridor to alleviate truck traffic related to goods movement from the ports.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

D2-c, d	Improve the Atlantic Bandini interchange, including truck ramps from the I-710 truck lanes and the southbound I-710 freeway, directly into the rail yards and truck ramps from the I-710 truck lane onto elevated truck lanes on Bandini Blvd. between 1-710 and I-5 to Garfield Ave. at the I-5 freeway.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

I-710 Major Corridor Study
Tier 1 Community Advisory Committee (CAC)

August-04

City of Compton	
ID#	**Community Ideas**
D4-a D6-a	Ensure that on-and off-ramps and adjacent streets are safe for both cars and pedestrians.
D6-a	Conduct a Pedestrian Analysis to determine the safety measures that may be needed on streets that lead to (or connect to) on-and off-ramps in Compton --particularly near schools..
D4-a	Improve the safety of the I-710 and 91 Interchange near Alondra. The west-bound 91 Freeway must be addressed.
H3-a	Fuel technology should be used to decrease air pollution.
E1-e	Ensure that Compton Creek will not be harmed from additional run-off resulting from freeway improvements. Provide stringent measures to against any potential pollution. Wildlife and plant life are vulnerable and must be protected.
N1-a	Sound walls should be provided to alleviate sound pollution.
i	Any widening and other improvements should take place on the east side of the I-710 through Compton. There should be no housing takes on the west side.
M4-a D3-c	Provide a by-pass for Compton and improve arterial highways that feed into the I-710.
D3-c	Ensure that major arterials are not adversely impacted by I-710 improvements.
D3-c	Analyze whether improvements are needed to improve the traffic flow on Atlantic, Alameda, Alondra, and Santa Fe, as all are important arterials in Compton.
M4-a D3-c	Consider placing restrictions for use of arterials that run through Compton. If use of these arterials are linked to I-710 improvements, there should be financial incentives provided to the city of Compton.
EJ2,3	The Port should provide financial incentives to the City of Compton for future proposed I-710 impacts that accommodate their growth.
D3-b	Ensure that truck-dedicated lanes on the freeway are located away from residential neighborhoods to avoid increased air pollution near homes.
D3-b	Keep elevated roadways away from residential neighborhoods.
M6-a	If elevated roadways are used, truck-designated roadways should be located on the lower level (to muffle the sound).

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

M2-c	Provide a light rail system along the I-710 with stops in Compton.
D6-a	Provide carpool lanes that lead more directly to Long Beach as it is a major destination.
ii	Explore the use of the riverbed for I-710 improvements.
E3-a	When construction is underway, provide advance warnings of detours and closures.
H4-b	Locate a truck facility in Compton--if it generates revenue for the City.
S4-d	Designate and identify specific alternate routes through Compton for drivers who must exit the freeway when accidents occur. Encourage use of these routes as much as possible to protect neighborhoods.
H4-f E1-f	Ensure that ramps are "green" Landscaping should be planted and maintained to beautify the area along the freeway. Establish a committee to monitor maintenance and accountability.
EJ3	For I-710 improvements, establish a requirement that Compton youth and adults must be hired on projects.
P3	Establish an ad hoc partnership, such as a Joint Powers Authority, between the City of Compton, and other I-710 Corridor Cities, Caltrans, and other public agencies involved with the I-710 improvements.
D4-a	Improve the safety of the I-710 and 91 Interchange at Alondra. Redesign the interchange to provide safer merging conditions.
D4-a	Provide an exit ramp to Rosecrans Avenue from the I-105 ramps.
H1-a-d	Addressing air quality and its improvement is a top priority for Compton.
EJ3	Explore using Compton residents to work on I-710 construction projects and provide training if needed.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

I-710 Major Corridor Study
Tier 1 Community Advisory Committee (CAC)

August-04

Note: The East Los Angeles Tier 1 CAC is still evaluating various ideas and options for the I-710 and I-5 freeways and have not yet made any decisions on improvements to those freeways until further studies are completed.

East Los Angeles

*ID#	Community Ideas
M2-c	Build a light rail system along the I-710 to relieve some of the auto congestion.
H3-f	Provide incentives, such as reduced fees, to encourage increased use of the Alameda Corridor and disincentives, such as increased fees/taxes, for truckers using the I-710.
H4-f	Beautify the I-710. Caltrans should maintain trash pick-ups, at a minimum, and provide landscaping.
D2-a	Double-deck the I-710 with truck-dedicated lanes.
EJ2	Encourage policy-makers to stress that San Gabriel Valley and South Pasadena must accept a more equitable share of the burden of traffic.
EJ2	Finish the I-710 through South Pasadena before making changes in our neighborhoods.
ii	Build a subterranean tunnel dedicated to truck traffic.
H4-c	Provide incentives for businesses to accept delivery during non-peak hours.
EJ1	Implement policies that encourage "land-use" trade-offs" and partnerships to allow shared parking or innovative solutions to eliminate truck parking in neighborhoods.
N1-a S4-a	Seek on-going funding for mitigation along the freeway, including soundwalls and concrete median barriers.
ii	Solutions must seek to resolve problems concurrently on both the I-710 and the 60 Interchange, as well as, the I-5 and I-710.
H3-a	Encourage technology that decreases toxic diesel emissions, such as the use of alternative fuels.
S4-b	Improve lighting along the corridor.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

East Los Angeles

*ID#	Community Ideas
M1-b	Encourage the Ports to implement 24/7 operations, **including negotiating with the Teamsters Union.**
M1-g M1-h	Limit truck traffic during rush hours and provide incentives to encourage more driving at night.
ii	Leave the Freeway as it is from Telegraph Road to the I-60 Freeway.
E1-a	Loss of open space due to freeways is a major concern.
ii	Tunnel under the freeway to provide truck dedicated lanes. Make it a toll-road to fund it.
ii	Interchange improvements are needed at the I-5 to I-710 southbound. Improve the on-ramp.
ii	Use a double-decker system within an existing right-of-way all the way to the I-210.
M1-f	Incorporate mass transit as alternatives to the freeway.
S2-b S2-c	Increase enforcement of speeding trucks.
S2-c	Trucks should use slow lanes only and second lane for passing only.
D2-a	Allow trucks to travel on dedicated lanes only.
S2-a	Increase enforcement of vehicles that don't meet regulations.
D2-a	Need to improve safety through design on Freeways.
S4-a	Add concrete barriers in the middle of the freeway.
M7-a	Disseminate goods through other ports--not just LA and Long Beach.
M1-c	Alameda corridor must be more widely used.
H3-a	Shift to alternative fuels.
H3-d, e, f	Require the use of alternative fuel for shipping.
H1-a	Conduct a study to evaluate air quality around schools. **With a baseline established, change can be monitored.**
H3-a	Outlaw use of diesel fuels.
EJ2, 3	Our community needs to have representation such as wealthier communities facing facing similar issues (101 freeway).
E1-a EJ3	Freeway improvements should result in community improvements such as parks, community facilities, local transit improvements.
D2-b	Provide off-ramps at rail yards.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

East Los Angeles

*ID#	Community Ideas
N1-a	Provide attractive and tall enough sound walls.
i	Address the area between Third and Sixth and McDonnell. There is dangerous double parking.
D3-a	East Los Angeles does not want any net loss in housing as a result of improvements to the freeway.
M2-a, b, c	Expand public transportation.
D3-c	Local streets that parallel the freeway need to be studied and improved.
H1-a - H2-f	Improvement in air quality is the number one priority for East Los Angeles.
ii	Examine other alternatives along I-5 (eliminate carpool lane or tunnel car pool lanes) to reduce property impacts in East Los Angeles.
ii	Determine impacts in East Los Angeles of proposed closure of I-710 Washington Boulevard interchange and mitigating impacts.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

I-710 Major Corridor Study
Tier 1 Community Advisory Committee (CAC)

Aug-04

City of Long Beach	
ID#	**Community Ideas**
	Community Approved Recommendations
i	Involve federal elected officials in the Freeway major corridor study.
i	The City of Long Beach should support Congress-member Rohrabacher's legislation to impose a fee on each container that enters the Port.
i	Do not move forward with the 710 Freeway project.
M2-d, e M3-b	Find an alternative to 710 Freeway expansion.
N1-a, b, c	Sound walls need to be included into the final budget for the 710 Freeway improvements, and they must be built at the time of construction of any improvements.
i	MTA and Caltrans should conduct a walk thru the Long Beach segment of the 710 Freeway where proposed improvements might take place.
EJ1	Minutes of all workshops should be translated in Spanish and Khmer.
i	No double decking of the 710 Freeway.
M4-b	School Bus traffic flow should not be impacted by future construction on the 710 Freeway.
S1-a S4-a	Center dividers must be built taller in the future.
	Health and Environment
H1-b	The Long Beach Health Department should conduct air quality studies near the intersection of the 710 Freeway and the 47 Freeway.
H3-a	School buses should use alternative fuels to reduce diesel emissions.
H3-a	The performance of alternative fuels on air pollution should be verified prior to commercial use.
i H1-d	City of Long Beach should review impacts of ICTF terminal to community ad local schools. Truck idling levels at the ICTF terminal should be reduced to the level of the Ports.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

E1-f E2-c E4-a H4-f	Increase tree plantings in Long Beach by threefold.
H1-d	Future health studies must include data about deaths related to pollution.
H1-d	The City of Long Beach should conduct research into the health impacts on the community stemming from local refinery emissions.
H1-d	The City of Long Beach should conduct research into the health impacts of diesel and other vehicle emission to children.
H1-d	The research should include asthma and other health ailments, including respiratory problems, cancer, allergies, etc.
H3-a, e, f	Trains should use cleaner fuels.
i	Signage should be visible to traffic at all times in the design of the 710 freeway.
H1-d	The City of Long Beach should conduct research regarding the impacts of pollution to local residents from Port operations, the 710 Freeway, local petroleum refineries, and the proposed Liquid Natural Gas station.
H4-d H2-c	Give incentive funding to truck operators to use bio-diesel.
N1-a, b, c N2-a - g	Noise pollution should be mitigated for any I-710 Freeway improvements.
H2-b, c	Trucks and ships delivering and hauling cargo from the Port of Long Beach should use particulate matter traps.
H3-a	A pilot project for the use of bio-diesel should be implemented.
	Port Operation and the I-710
H4-e M5-c M7-a	A limit on Port expansion should be discussed.
M5-a	Tariffs should be imposed on businesses that use the port. The funds gathered through the tariffs should be utilized for programs to clean air pollution.
H2-b H2-a H3-d H4-d	Trucks operating at the Port should use bio-diesel or alternative fuels.
i	Shipping companies should hire independent truck drivers as employees and they should treat them fairly.
M1-d	On-dock rail capabilities should be expanded.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

H2-d	The Port should pay for any impacts to the community, including any improvements to the 710 Freeway and impacts to the health of residents in the community.
i	All empty containers should be shipped to the place of origin and they should be allowed to remain empty in the Port.
i	The City of Long Beach should research the impacts of Port expansion to the local tourism industry.
H2-d M5-a D1-b,c	Extra fees should be charged to Port tenants and companies hauling cargo from the Port to cover expenses related to local healthcare costs.
H3-a H2-b	The Port should support the use of green diesel and compressed natural gas for trucks hauling cargo from the Port.
H2-b N3-b	The Port should develop aggressive idling legislation to limit diesel truck idling to a maximum of five minutes.
M7-a	Cargo should be distributed to other regional Ports.
M7-a H4-e, i	The Port of Long Beach should be downsized.
M7-a H4-e, i	The City of Long Beach should define the maximum capacity of the Port of Long Beach.
M1-b, c, d	The Alameda Corridor Transportation Authority's initiatives should be implemented immediately.
H1-d	The Port should not extend to a 24-hour operation until further air quality research is conducted on the potential impacts to Long Beach residents.
H2-b	Governing agencies should make it mandatory for ships to slow down as they prepare to dock at the Port of Long Beach.
H2-b	By 2006, offshore shipping companies should be equipped to use shore power while docked at the Port.
i	Cargo containers should be standardized which would allow multiple companies to use the containers and reduce the number of empty containers at the Port.
i	The Port of Los Angeles should participate at the next workshop related to Port Operations.
H2-b	Local Ports should coordinate the use of alternative fuels strategies.
H1-c	The Port should conduct research on the cost of pollution to local healthcare.
M1-c, d M2-d	Identify alternative methods to haul cargo from the Port- other than diesel trucks.
H2-b	Ships should be made to slow down when entering the Port.
H2-b	Diesel emissions from sea vessels and trains need to be addressed by regulatory agencies.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

H2-b	Ships should use alternative fuels when docking at the Port of Long Beach.
	Preserving Neighborhoods
i	Residents should have free and competent legal advice provided to them to assist them with the property acquisition process.
EJ-3	Residents whose property is not taken but impacted by 710 Freeway improvements should be compensated by Caltrans.
EJ1	The City of Long Beach and Caltrans should inform residents about any property acquisition plans in advance and a timely manner.
i	The public should be provided an opportunity to view and comment on the new 710 Freeway designs at various public meetings.
M2-d, e	Do not take any businesses or homes until all other alternatives and options for improving the 710 Freeway are exhausted.
i	Caltrans should better maintain the properties they currently own in Long Beach.
EJ3 E3-b	Caltrans should establish a performance bond for any improvements to the 710 Freeway that would allow for residents to recoup any damages during construction.
EJ1	Residents should be encouraged to attend meetings about the 710 Freeway and they should continue applying pressure and giving input on this process.
EJ1	Properties should be referred to as "homes" and not "houses" during discussions about 710 Freeway improvements.
EJ1, 3 E3-b	Caltrans should provide contact information to residents about whom to contact regarding damages done to properties because of construction to the 710 Freeway.
EJ3	An appraisal should be conducted at the time of the final design for the 710 Freeway improvements and a second appraisal should be conducted at the time that Caltrans begins the property acquisition process.
i	Conduct community meetings in the first district to make it easier for residents in that district to attend meetings.
	Truck Congestion and Safety
M5-a D1-b D1-c S1-c	A toll on diesel trucks should be imposed to offset the cost of utilizing the Alameda Corridor.
D3-b	Study the spillover traffic and the 710 Freeway. The spillover traffic may create safety issues for pedestrians.
M1-c	A shuttle trail system should be developed to haul cargo to local distribution centers in Southern California.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

M3-b	Use the Terminal Island Freeway and the Alameda Corridor to haul cargo and divert diesel trucks away from the 710 Freeway.
M4-a	The 103 Freeway should be expanded and should proceed left on Sepulveda and Willow and connect to the Alameda Corridor.
M4-a	Encourage the use of the 110 Freeway to divide truck traffic equally with the 710 Freeway.
M4-a	The City of Long Beach should establish a transportation policy to divert truck traffic to routes other than the 710 Freeway.
M5-a D1-a, d, c	A toll shall be implemented on trucks hauling cargo from the Port and shipping companies should pay a toll.
H2-a	A new truck inspection site should be built on Port of Long Beach Property.
i	Truck drivers should be considered when developing new cargo hauling methods.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

I-710 Major Corridor Study
Tier 1 Community Advisory Committee (CAC)

August-04

City of Lynwood	
***ID#**	**Community Ideas**
ii	Install surveillance cameras at areas known to be unsafe in order to reduce hit-and-run accidents and dangerous, illegal driving behavior.
D2-a	Minimize trucks accidents by separating truck/auto traffic.
S3-b	Improve safety by implementing public education campaigns aimed at increasing awareness of how to share the road safely with trucks, and through greater enforcement and emphasis on adequate truck driver training and licensing.
ii	Explore the possibility of constructing a truck-dedicated elevated roadway above the riverbed that runs parallel to the I-710.
ii	Double-deck the I-710 freeway with truck-dedicated lanes.
M2-c	Support a light rail system that follows the course of the I-710. Provide stations that are easily accessible for Lynwood residents.
E1-f	Provide landscaping along the freeway in Lynwood. Ensure that landscaping creates an aesthetically-pleasing, safe environment.
S4-a	Extend the median barriers along the entire stretch of the freeway.
M1-h	Limit truck traffic hours.
D4-b	Improve access to Lynwood by creating more off-on ramps.
ii	Explore utilizing Alameda and Imperial as the major mobility corridors for through-truck traffic.
M1-h	Limit the hours of operation of trucks and increase fees during peak hours.
ii	Build a truck-designated roadway within the LA River.
M1-e	Lower fees to promote increased use of the Alameda Corridor for goods movement.
N1-b	Build sound walls along the entire I-710 to buffer noise in residential areas. Where necessary, use similar sound mitigation measures that airports employ.
S4-b	Improve existing lighting/add new lighting on the I-710.
i	Study Josephine, Rosecrans, Martin Luther King Boulevard, Abbott, and Carlin to determine traffic flow improvements that are needed (as part of the EIR process.)
H3-a	Provide more stringent air quality standards that address the excessive pollution generated by diesel-using trucks.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

City of Lynwood

*ID#	Community Ideas
E2-b	Beautification of areas through landscaping and maintenance of landscaping should take place, particularly beneath the cloverleaf portion of the I-710 (in Lynwood) that may be reconfigured as a future improvement (see Jerry Wood's concept drawings)
D4-a	Provide more on/off ramps from the I-105 to Lynwood at Atlantic Ave. and also Alameda St..
i E3-a	Conduct a pavement analysis of city streets before and after construction of arterial and I-710 improvements to assess whether damage has occurred. If streets have been damaged, the responsible agency/entity shall pay for and undertake repair in a timely manner.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

I-710 Major Corridor Study
Tier 1 Community Advisory Committee (CAC)

August-04

City of South Gate	
***ID#**	**Community Ideas**
M1-a	Synchronize traffic signals along arterials and major streets for better mobility and to less congestion.
D4-a	Reconstruct Imperial/I-710 interchange to establish diamond lanes similar to Firetstone/1-710.
N2-e	Mitigate noise and dust during construction.
S4-c	Adequately mark and provide signage for truck routes.
N1-a	Construct decorative sound wall and safety shields along the freeway adjacent to affected residents and businesses.
E2-c	Include landscaping along the (I-710) freeway especially at interchanges and soundwalls.
i	Provide a three dimensional model of the proposed I-710 Freeway improvement in the City of South Gate.
i	Provide a time schedule that includes sequence of construction work in South Gate.
M4-c	Establish ways to minimize inconvenience to residents and businesses during construction.
EJ2	Provide incentives to residents and businesses that have been and will be suffering depreciation and (loss of) income during construction of the freeway.
M1-h	Install ramp metering for trucks at the port of Long Beach.
ii	Establish a (800) number with a bilingual live person responding throughout this project so anyone can call with questions. Consider using television, internet, radio and other media fro keeping the community informed of the project status through completion.
P3	Continue including Tier 2 on the corridor improvements through project completion including but not limited to design, construction staging (especially establishing detour routes during construction.
D3-c	Extend Southern Avenue under or over the freeway and increase Southern Ave. Lane width to four lanes (two lanes each direction) for better mobility and to reduce local traffic from Firestone.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

City of South Gate

*ID#	Community Ideas
D4-c	Widen Garfield Avenue Bridge over the Rio Hondo River and associated sidewalk along Garfield.
M2-b	Consider using additional bus transportation on Garfield between Firestone and Imperial.
EJ2	Provide fair and expedient negotiations with property owners that must move due to the proposed project. In the event of partial takes, efforts should be made to replace the property taken with property contiguous with that remaining.
i M4-b	Avoid impacts to local businesses including Security Public Storage South Gate Facility, Scully-Miller and Rockview Farms.
ii	Prior to major freeway construction surface street repairs, upgrades and improvements should be scheduled and completed. This work should be undertaken on all surface streets within the corridor that will be impacted traffic diverted from the I-710 during construction and should include refinement of the traffic control system.
D2-a	Rockview supports the inclusion of "truck only" lanes as part of the project.
D4-c	Include the installation of a Southern Ave. Bridge over the I-710 thereby connecting east with west South Gate. This bridge would relieve traffic on Firestone Blvd. and provide a second exit on for the Thunderbird Mobile Home Park.
M4-a	Provide advance and continuous public notice of road closures, detours and other changes to traffic flow. Include accommodations for emergency services, truck and business traffic signage directing customer traffic to businesses.
E1-f	Develop a freeway design that includes beautification of the right of way with a separate identity for each city through which the freeway passes.
i	Maintain access to Sully-Miller Construction by providing the same number of driveways.
D3-c	Study parallel arterial highway and determine needed improvements prior to major construction of the freeway.
i	Improve air quality and reduce diesel emissions.
M1-b	Support extended hours of operation at the ports and moving more cargo by rail, potentially the Alameda corridor.

Xx-x - reference to the ID number found in the Strategies Summary Matrix
i - Local city issues to be addressed with the city during the environmental phase
ii - Ideas considered by Tier 1 CACs but not carried forward to Tier 2 CAC

APPENDIX D: TRAFFIC ASSUMPTIONS; TRANSLOAD COMMENTS AND REPORT

1. EXCERPTS FROM MINUTES OF I-710 CORRIDOR EIR/EIS PROJECT COMMITTEE
2. Transload Report by Andrea Hricko
3. Journal of Commerce transload statistics

1. EXCERPTS FROM MINUTES OF I-710 CORRIDOR EIR/EIS PROJECT COMMITTEE

THE MINUTES OF THE MEETING OF THE
I-710 CORRIDOR EIR/EIS PROJECT COMMITTEE
A Meeting Held at Progress Park
15500 Downey Ave.
Paramount, CA
January 30, 2014

Excerpt from the Minutes:

B. I-710 Traffic Forecast Update

Dave Levinsohn, URS, gave a PowerPoint presentation which summarized changes to the traffic model since the release of the Draft EIR/EIS. He identified key travel demand inputs that had been updated, including the SCIG and ICTF projects, new understanding of the transload truck patterns, the 2012 SCAG RTP travel demand model, and port cargo projections. Overall, the 2012 SCAR RTP model shows lower projected port truck volumes and greater volumes of non-port trucks on I-710 than the 2008 SCAG RTP model.

MINUTES OF THE MEETING OF THE
I-710 CORRIDOR PROJECT EIR/EIS
TECHNICAL ADVISORY COMMITTEE
16401 Paramount Blvd., Paramount, CA
June 19, 2013

Excerpt from the Minutes

Jerry Wood commented that the traffic forecasts will be analyzed with and without the near-dock rail yards, with and without the SR-710 north extension, and including new multi-modal and active transportation plans inputs, and new rail yards and transloading facilities information that has recently been developed or become available.

MINUTES OF THE MEETING OF THE I-710 CORRIDOR EIR/EIS PROJECT COMMITTEE

A Meeting Held at Progress Park

15500 Downey Ave. Paramount, CA

May 30, 2013

Excerpt from the Minutes:

Gill Hicks, Cambridge Systematics, gave a PowerPoint presentation regarding the goods movement assumptions. He said the SCIG and ICTF rail yards are now included in the No Build and various build alternatives. He said reductions had been made in the container volume at intermodal yards and the daily trips of automobiles to the ports. Mr. Hicks explained the projections for annual lifts at the intermodal rail yards and gave a detailed description of how and where transloading of marine containers takes place. Because of the advance in information systems, the revised EIR/EIS will assume a greater level of truck double-cycling and empty chassis re-use at intermodal yards. He said the next steps will include forecast modeling and a report on the initial model runs.
Patricia Ochoa, Coalition for Clean Air, read a letter from the Coalition for Environmental Health and Justice. She said the recommendation is that more time be taken to analyze the traffic assumptions before presenting them to the Project Committee.

Patricia Ochoa, Coalition for Clean Air, read a letter from the Coalition for Environmental Health and Justice. She said the recommendation is that more time be taken to analyze the traffic assumptions before presenting them to the Project Committee.

Angelo Logan, East Yard Communities for Environmental Justice, said this is very important and complicated. He said their recommendation is to take pause and allow this information to be well-vetted by all stakeholders.

MINUTES OF THE MEETING OF THE I-710 CORRIDOR PROJECT EIR/EIS TECHNICAL ADVISORY COMMITTEE 16401 Paramount Blvd., Paramount, CA August 21, 2013

Mr. Hicks said the 2035 forecast is for 110,000 daily truck trips to and from the ports and for 17,000 daily trips involved in transloading of port-related goods. He said the forecast is for an additional 14,000 intermodal daily trips that are not port-related and 172,000 daily non-intermodal truck trips in the I-710 study area that are not port-related. He said the 2035 numbers reflect a reduction from the previous forecast from 43.2 million to 41.4 million containers coming through the ports.

THE TRUCK AND TRANSLOAD REPORT:

An analysis

of unverified assertions and untested assumptions

in the BNSF SCIG DEIR

concerning future activities at the BNSF Hobart Yard

if the BNSF SCIG opens

Report submitted as comments
to the POLA on the SCIG DEIR
by
Andrea Hricko, MPH*
Professor of Preventive Medicine, Keck School of Medicine, USC
& Director of the Community Outreach and Engagement Program
of the Southern California Environmental Health Sciences Center

February 1, 2012

** A first draft of this report was completed by Andrea Hricko and Ariella Morrow in 2007, when Ms. Morrow was a graduate MPH student at USC Keck School of Medicine. Ms. Morrow is currently a medical student and has not reviewed the recently issued Draft Environmental Impact Report. We acknowledge her work and earlier efforts.*

Summary

BNSF Railway has proposed a new intermodal rail facility to be located "near-dock" -- four miles from the Ports of Los Angeles and Long Beach. A Draft Environmental Impact Report (DEIR) has been issued. That report concludes that the new rail yard, called the Southern California International Gateway or SCIG Project will reduce truck traffic, improve air quality and improve health in the region.

This analysis examines the assertions in the DEIR about how the claimed reduction in truck traffic will be accomplished. It examines the assumptions in the DEIR upon which other analyses (e.g., air quality) are based. It explores what might happen to the BNSF Hobart Yard if the SCIG opens, with claims in the DEIR stating that Hobart will handle only "domestic" containers and will no longer be handling any more than 5% of international cargo, thereby "shifting" trucks from the I-710 and I-110 Freeways a shorter distance to the new SCIG.

Definitions play a role in claims in the DEIR. It is important to note that "domestic containers" can be of two types:

- Transloaded containers - cargo that arrived at the Ports and was then taken out of the 40-foot containers at a transload facility and then placed into 53-foot containers before arriving at a rail yard, and
- "Pure" domestic cargo in either domestic 53-foot containers or trailers – cargo that has not passed through the Ports before arriving at the rail yard. *(See DEIR at 3.10-31)*

The analysis concludes that those who drafted the DEIR and supplied information for it (POLA, Environ, and BSNF) failed to consider the most recent trends in the industry with regard to a "surge" in transloading of international containers, a practice increasingly popular with retailers that has been well-reported in the logistics industry press and in goods movement reports. According to the director of the Alameda Corridor Transportation Authority, a full 25% of imported cargo containers from the Ports of Los Angeles and Long Beach are now transloaded into domestic containers before they leave Southern California on rail. The author concludes that by 2016 the BNSF Hobart Yard would have the opportunity to "replace" the volume of "lifts" (containers) that go to the new BNSF SCIG yard with transloaded containers. If this happens, it would mean that there will likely be no "reduction" in truck mileage on the I-710 when the SCIG opens. In fact, the volume of trucks on the road to the two railyards (SCIG and Hobart) would be double the volume that had gone to the BNSF Hobart Yard alone. Several scenarios are included in this report.

The analysis concludes that the assertions in the DEIR about 1) reduction of truck trips to the BNSF SCIG, including information about the volume of transloaded containers and other information about what the "domestic containers" will comprise, are undocumented, 2) the assumptions are untested, and 3) the conclusions in the DEIR about traffic and air pollution impacts – which are based on these assumptions – are inaccurate.

Using documented and up-to-date information about trends in transloading, this Truck and Transload Report concludes that by 2016 the BNSF Hobart Yard will have the opportunity to replace with transloaded "domestic" containers all the "truck trips" that would supposedly have "been eliminated" by switching international containers from Hobart to the new BNSF SCIG.

In addition, there will be nearly an equal number of trucks by 2016 to the Hobart Yard and to the new BNSF SCIG, indicating that there could be twice as much truck traffic on the Harbor area's roads and freeways than the DEIR claims.

More detail: as calculated in this report, based on Port cargo forecasts in the SCIG DEIR, there might be as many as 1,202,500 transloaded containers available for the Hobart Yard in 2016, meaning that the number of transloaded containers by 2016 could replace the number of international containers moved to SCIG in 2016 (projected at 1.1 million). This would indicate that all of the traffic counts in the DEIR are faulty. If the Hobart Yard is going to continue handling transloaded containers (which it already does, but which the DEIR fails to describe), then there will be no reduction of truck trips and miles on the I-710 Freeway assuming that imported cargo grows as forecasted and that transloading continues to capture an ever-growing share of how imported cargo leaves the Ports.

In addition, the distance from the Port to a typical transload center and then on to Hobart with a transloaded domestic container is more than the current 24 miles that trucks travel to deliver international containers, because of the diversion off the I-710 to the transload facility and often then back onto the I-710. This transload scenario makes all the calculations in the SCIG DEIR about reduced truck traffic along the I-710 questionable**.**

The author of these comments recommends sending the DEIR back to the drawing board, redoing it and recirculating it, and requiring that all of the unverified assertions and untested assumptions be fully documented – and that all analyses, including air quality impacts, traffic impacts, cancer risk in the HRA, cumulative impacts and other impacts of the proposed SCIG, based on these assertions and assumptions, be fully redone.

THE REPORT

We appreciate the opportunity to offer comments on the BNSF SCIG DEIR and have chosen to look at the truck, traffic and transloading issue in the form of a report.

What does the DEIR say about the proposed BNSF SCIG project and the future of the existing BNSF Hobart Yard?

The Southern California International Gateway ("SCIG") rail yard project is an intermodal rail facility proposed by the BNSF Railway and the Port of Los Angeles (POLA) that would increase the ability of both POLA and the Port of Long Beach to grow. The POLA released the project's Draft Environmental Impact Report (DEIR) in September 2012, with comments due on February 1, 2011.

The DEIR was prepared by Environ International. The DEIR's analyses of potential air quality impacts, traffic impacts, cancer risk, cumulative impacts and other impacts of the proposed SCIG all heavily rely on assertions in the DEIR about BNSF's major Southern California rail yard, Hobart, the country's largest intermodal facility, which is located 24 miles from the Ports at the northern end of the I-710 (Long Beach) Freeway. Drayage trucks will be "shifted" from Hobart to the SCIG, saving miles traveled and reducing air pollution, according to the Draft EIR:

*"The proposed Project would construct an intermodal transfer facility at a location approximately 4 miles from the Ports, the proposed Project would eliminate a part (estimated at 95%) of existing and future intermodal truck trips between the Port and the BNSF's Hobart Yard, which is located approximately 24 miles north of the Ports in the cities of Los Angeles and Commerce, by diverting them to the proposed SCIG facility." (*DEIR at 3.10-30) (emphasis added)

The DEIR continues:

*"On the I-710 freeway … it is estimated that the project will reduce over 1.3 million truck trips per year…. This is due to the fact that the trips will occur to SCIG rather than to Hobart Yard, thus eliminating the trips on the I-710." (*DEIR at 3.10-26 (emphasis added).

In addition, the DEIR states:

"The proposed Project would result in fewer truck trips on the surrounding freeway system, as drayage operations currently serving the Hobart Railyard near downtown Los Angeles utilizing I-110 and I-710 north of the Pacific Coast Highway would be switched to the proposed Project site utilizing the proposed Project truck routes. Thus, the existing longer-distance freeway system trips from the ports to downtown rail yards would be replaced by shorter-distance trips to/from the proposed Project along port-area roadways." DEIR at 3.10-45) (emphasis added).

The DEIR does state that a small number of international containers will still go to the Hobart Yard, indicating that the Yard will not be closing:

*"The baseline intermodal demand handled by the Hobart Yard would be handled by the proposed Project. In order to be conservative, some international container trips are assumed to be handled by the Hobart Yard under proposed Project conditions – five percent of the baseline operations."(*DEIR at 3.10-40, emphasis added).

And finally, below is a description of how the DEIR says it used all of these alleged shortened traffic routes to evaluate air pollution and other impacts:

"These changes in traffic patterns, which are evaluated in this EIR, are being proposed in order to shorten truck trips for movement of containers between ships and railyards), thereby easing traffic conditions on local freeways and reducing regional air quality impacts. On the I-710 freeway, which is the primary roadway facility that services current Hobart Yard traffic, it is estimated that the project will reduce over 1.3 million truck trips per year between the SCIG project site and the BNSF Hobart Yard. This is due to the fact that the trips will occur to SCIG rather than to Hobart Yard, thus eliminating trips on the I-710." (DEIR at 3.10-26) (emphasis added)

What types of cargo are <u>currently</u> handled at the BNSF Hobart Yard – in 2011?

The DEIR states the following about the BNSF Hobart Yard and other intermodal rail yards in the Ports area: (See DEIR at 1-13).

Off-Dock Rail

Off-dock railyards are located farther (more than five miles) from marine terminals. Currently, there are a total of five off-dock railyards, three operated by UP and two operated by BNSF, but only two handle substantial numbers of containers from the San Pedro Bay Ports: the BNSF Hobart Yard in Los Angeles/Commerce/Vernon and the UP East Los Angeles Yard (Figure 1-8). Both railyards are located near downtown Los Angeles, approximately 24 miles north of the Ports. The remaining off-dock railyards include the UP Los Angeles Trailer and Container Intermodal Facility (LATC), UP City of Industry yard, and the BNSF San Bernardino yard. In 2008 the East LA and Hobart yards handled most of the international cargo not handled by on-dock yards and the ICTF: 136,000 TEUs by East LA and 1.48 million by Hobart, which currently handles all of BNSF's non-on-dock international cargo. All of the off-dock railyards in the region, including Hobart, handle more domestic and transloaded containers than international containers.

Key Definitions

Off-Dock Railyard: railyard located more than five miles from a marine terminal.

We note that the last sentence in the DEIR above states that: **"All of the off-dock railyards in the region, including Hobart, handle more domestic and transloaded containers than international containers."** This statement is interesting in several ways. First, it is an admission that the Hobart Yard currently handles transloaded containers. But the statement is factually incorrect with regard to the makeup of the overall container load at Hobart – something that is critical to the DEIR's calculations. Using information from BNSF, **the California Air Resources Board and Los Angeles County Metropolitan Transportation Authority both show that at the Hobart Yard, 59% of the containers handled are international containers and 41% are domestic (including transloaded and "pure" domestic).**[i] That is, there are currently more international containers at Hobart Yard than domestic and transloaded containers. It seems odd in a DEIR of this magnitude to have such a basic fact about the BNSF Hobart facility be completely wrong. See figure from L.A. County Metro below:

Table A-6
UP and BNSF Intermodal Off-Dock Railyards
In the South Coast Air Basin
International vs. Domestic Containers

Railyard	International Containers (Port Containers)[a]	Domestic Containers (Non-Port / Warehouse / Transloading)[a]
BNSF San Bernardino	0%	100%
BNSF Hobart (includes BNSF Commerce/Eastern)	59%	41%
UP Commerce	24%	76%
UP ICTF/Dolores	100%	0%

B Basis for Emission Control Factors

The Union Pacific Intermodal Container Transfer Facility (UP ICTF) handles only international cargo containers. There are three large rail yards (and one small yard) north of the Ports that handle a combination of international containers, domestic containers, and transloaded containers, as shown in Table 1.

Table 1. Rail Intermodal Throughput Capacity, Adapted from Metro Table[ii] and California Air Resources Board[iii]

Facility	Capacity Lifts	2006 international lifts	Percent of Yard That is International Container Traffic	Percent of Yard That Handles Domestic Containers (Pure Domestic and Transloaded Domestic)
BNSF Hobart	1, 500,000*	808,086	59%	41%
UP East Los Angeles/Commerce	510,000	80,108	24%	76%
UP LATC	340,000	32,912	16%	84%
BNSF Eastern*		130,000 (2004)		

**BNSF counts capacity at this yard as 1.7 million, but the actual capacity according to the ARB is 1.5 million lifts. The rest is related to the BNSF Commerce Eastern yard, according to the ARB. The BNSF Eastern yard focuses on local domestic containers and handled 130,000 lifts in 2004, according to the California Air Resources Board.* http://www.arb.ca.gov/railyard/hra/bnsf_eastern_hra.pdf

Table A-5
Four High-Priority Railyards
Container Lift Activities, Forecasts, and Capacities
(April 2011)

Railyard	2005 (lifts) Actual	2010 (lifts) Actual	2015 (lifts) Projected	2020 (lifts) Projected	Annual Percent Growth from 2011 to 2020	Railroad Stated Capacity (lifts)
BNSF San Bernardino	555,000[a]	447,000[c]	546,000	668,000	4.1	660,000[e]
% change from 2005	–	-19%	-1.6%	+20%	–	–
BNSF Hobart	1,336,000[a]	1,090,000[c]	1,386,000	1,763,000	4.9	1,500,000[e,f]
% change from 2005	–	-19%	+3.6%	+32%	–	–

b. Union Pacific Fact Book, 2005, p. 9.
c. ARB staff, Harold Holmes, Personal communication with BNSF via email (January 17, 2011).
d. Union Pacific Fact Book, 2010, p. 15.
e. Los Angeles County Metropolitan Transportation Authority, *Technical Memorandum – I-710 Railroads Goods Movement Study, WBS Task ID:150.10.50*, February 2009, pp. 22-24.
f. Based on personal communications between BNSF and Harold Holmes via phone on May 20, 2011, staff determined that 1.5 million of 1.7 million lift capacity was attributed to BNSF Hobart Railyard only, with the balance attributed to BNSF Commerce/Eastern Railyard.

What are current transloading trends at the Ports of L.A. and Long Beach, what does the DEIR say about transloading, and why does transloading matter to analysis of the DEIR's assertions?

There is a surging industry trend: the practice called "transloading." The trend involves switching the contents of international containers into domestic containers at a location north of the Ports, in the 25-mile stretch between the Ports and the Hobart rail yard.

It works this way: 3 big-rig trucks pick up three international containers at the Ports. The containers are driven a few miles or up to 24 miles north of the Ports, and they are dropped off at a "transload center." At the transload center, the contents of the 20 or 40-foot "international" containers are emptied. The goods are then reloaded into 53-foot "domestic" containers. This trend is valuable for the retail industry, because the contents of 3 international containers fit into 2 domestic containers, reducing shipping costs and allowing for greater flexibility in selecting destinations for cargo once it has arrived in California.[iv]

The 53-foot transloaded "domestic containers" may "appear" to be "domestic" but <u>they are full of international goods.</u> And these transloaded containers travel at least 24 miles to get to the Hobart Yard.

The DEIR virtually ignores the latest trends in the goods movement industry with regard to transloading of international containers; in fact, the DEIR's statistics are based on completely outdated figures. The DEIR has a table (See Table 1-2 below) citing transload statistics,[v] referring to an unidentified source or report, simply "POLA, 2009." The text states that: "… approximately eight percent of import containers are transloaded to domestic international containers, a portion of which may then be drayed to an intermodal railyard for transport by rail to their eastern destinations." It also cites the Table 1-2 below as data used in developing intermodal rail forecasts. (See DEIR at 1-21).

Table 1-2. Mode Split of Containers Handled at the Ports of Los Angeles and Long Beach in 2008.

Container Mode	TEUs (Millions)	Percent of Total
Direct Rail (Direct Intermodal)		
- On-Dock	(3.4)	(23.7)
- Near-Dock	(1.06)	(7.4)
- Off-Dock	(1.68)	(11.1)
Total Direct Rail	6.14	42.2
Transload	1.12	7.8
Local/Domestic (Truck only)	7.07	50.0
Total	14.33	100%

Source: POLA, 2009.

:

Contrary to the claimed 2009 statistics cited in Table 1-2 (above) of the DEIR showing 7.8% transloaded containers, currently a full 25% of cargo coming into the Ports is transloaded to rail, according to the head of the Alameda Corridor Transportation Authority (ACTA), John Doherty). In an email exchange with the author of these comments, in October 2011,[vi] Mr. Doherty stated the following:

"Another simpler way of expressing the data (thereby avoiding the confusion of whether you are talking about % of outbound rail imports or % of port total imports) is as follows: about 40% of port imports go out of state by rail as ISO containers (20', 40', 45') with no transloading, about 25% go out by rail after transloading (48' and 53'), about 10% go out of state by truck after transloading (48' and 53'), and about 25% stay local both with and without transloading." *(John Doherty, ACTA, October 2011)*

The following table reflects the statistics from Mr. Doherty, which are his conclusions after having interviewed more than 100 shipping and transload experts.

Table 2. Where POLA and POLB Cargo Goes and by What Mode	
Mode	**%**
Out of state by rail in ISO containers (20', 40', 45') – with no transloading	40%
Out of state by rail after transloading into 48' and 53' containers	25%
Out of state by truck after transloading (48' and 53')	10%
Stay local both with and without transloading	25%
TOTAL CARGO	100%

The current documented statistic of 25% transloading of containers entering the Ports of LA and Long Beach versus the DEIR's statistic of 7.8% transloading (shown in DEIR Table 1-2) indicates a 320% error in the DEIR.

We note that in another section of the DEIR, a figure of 25% transloading is mentioned, with no citation, but the DEIR does nothing to explain the discrepancy with the 7.8% figure. The DEIR claims to use the 25% figure in calculating freight rail volumes for 2035. It does not discuss using either the 7.8% figure nor the 25% figure in doing any calculations about what the future will hold specifically for the Hobart Yard. See DEIR

at 4-92, reprinted below:

> Specifically, year 2035 freight rail volumes were developed using projections for direct intermodal containers from the ports (intact containers that are not transloaded); projections for non-intermodal port rail shipments (bulk, automobiles, and carload traffic); transloaded cargo containers (estimated, on the basis of historical data and recent SCAG studies, at 25 percent of all import containers; the I-170 EIR/EIS and current work being conducted for the SCAG 2012 RTP use this same assumption); non-port rail data and projections being developed for the 2012 RTP; historical lift data, by railyard, of marine and non-marine containers at off-dock railyards; off-dock railyard capacities (see Section 1.1.5.3); and volumes of domestic cargo in 53-foot containers or trailers that has not passed through the ports. Consistent with the ongoing I-710 EIR/EIS technical studies, a reasonable growth factor of two percent per year was assumed. The cumulative rail volumes also include 2035 projections of passenger trains, based upon data from SCAG and MetroLink. Rail volumes for 2046 were estimated by assuming that the growth in rail volumes beyond 2035 will come only from increases in domestic freight rail traffic.

The *Journal of Commerce*, the premier logistics industry journal, has written a number of articles about the dramatic surge in transloading, especially at the POLA and POLB:

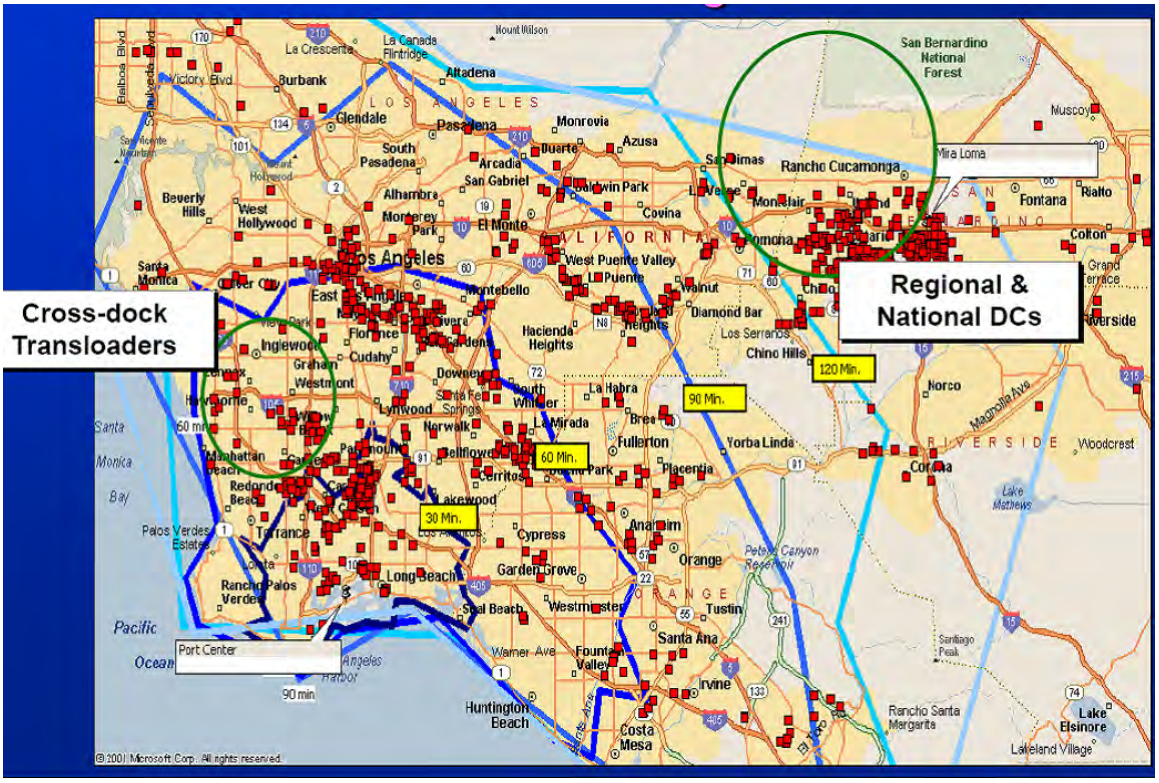
> *… "In an attempt to control transportation costs, retailers transload 40-foot marine containers into 53-foot domestic containers for inland movements. The contents of three marine containers can be loaded into two domestic containers."*[vii]

> *""… transloading took off during the recession, particularly at the ports of Los Angeles and Long Beach. According to the Alameda Corridor Transportation Authority, the share of goods arriving at LA-Long Beach transloaded into domestic containers grew significantly during the recession…. "That means that transload has a greater market share now. The pendulum has swung to transload," said John Doherty, CEO of the authority.""*[viii].

If, as noted above, 25% of imported cargo containers are being transloaded, where are the calculations in the DEIR that explain how this will impact/affect the NBSF Hobart Yard in the future? The author of this report cannot find such calculations.

The *Journal of Commerce* describes several reasons why retailers are embracing transloading:

> *"There have always been obvious economic benefits — transloading allows the contents of three international containers to be reloaded into two larger 53-foot trailers or domestic containers. … When the recession hit and shippers large and small went searching for transportation savings, transloading was a ready-made opportunity."*[ix]



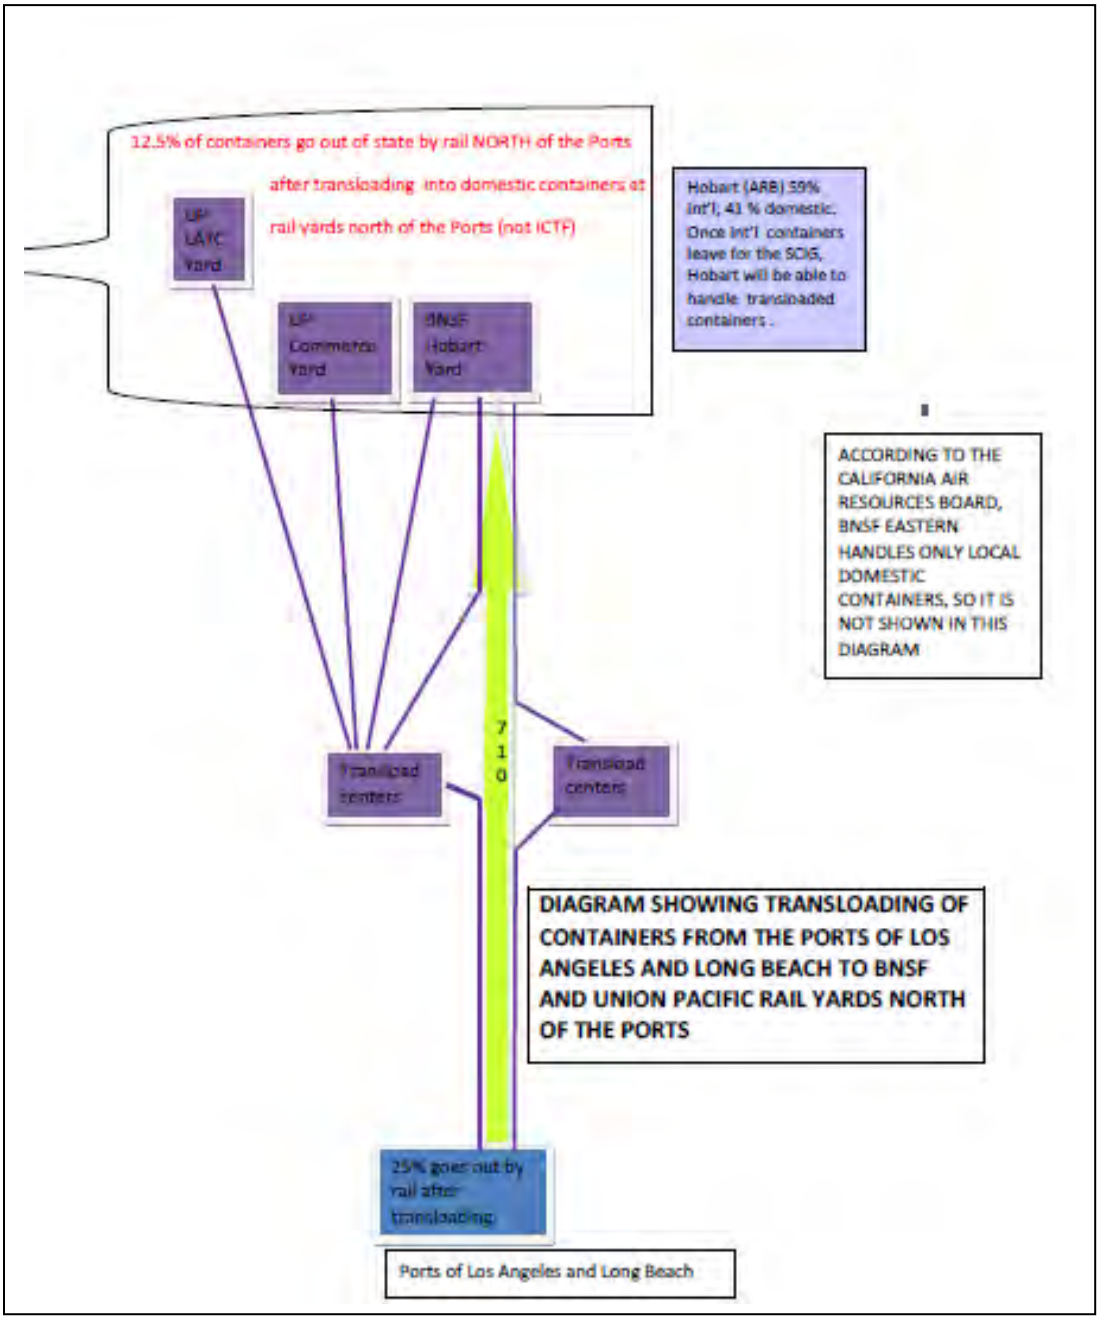
Lest anyone think that this transload trend might not have been common knowledge in the ports/logistics/rail industries long before the *Journal of Commerce* articles in 2011 (and long before the DEIR was released), please see the following excerpt from a Tioga Group report in 2008:[x]

> *"The Transload segment will be largely confined to the region between the Ports and downtown Los Angeles. This segment includes cargo that is "cross-docked" from international containers to domestic containers or trailers for onward movement by rail*

without spending significant time in inventory or undergoing value-added alterations. This cargo is typified by the Maersk Logistics activity in South Gate (Exhibit 11. As the aerial photo shows, this facility consists primarily of two-sided transfer sheds suitable for the "cross-dock" transfer operation, with minimal if any space for "warehousing…"…such operations are clustered within 15 miles of the Ports to maximize round-trip drayage productivity. Tioga studies have reinforced this finding."[xi]

See also the following reference, which states that as early as 2004 – 8 years ago – a full 12% of cargo was transloaded according to a 2004 study by the Alameda Corridor Transportation Authority (ACTA),[xii] which is also referenced in the 2006 Multi-County Goods Movement Action Plan (McGMAP).[xiii] The McGMAP report includes the following graphic, showing the high volume of transload facilities north of the the POLA/POLB and in the vicinity of the Hobart Yard. [xiv]

Figure 1. Transload Facilities North of the Ports in Los Angeles; McGMAP 2006.



The current surging transload trends are anticipated to continue,[xv] and if they do, this report calculates that transloading will allow the BSNF Hobart Yard an opportunity to replace the volume of containers that was diverted to the SCIG by 2016, if the SCIG becomes operational.

The graphic below shows the location of the major railyards in southern California that handle cargo from the Ports:

The sketch below shows the major rail yards handling transloaded cargo north of the Ports.

Figure 2. Major Railyards in Southern California Handling Cargo that Originated at the Ports (either in International Containers or Transloaded)

Sketch by Andrea Hricko

WHAT WOULD HAPPEN IF THE HOBART YARD TOOK ONLY DOMESTIC (NON-TRANSLOADED) CONTAINERS ONCE THE SCIG OPENS, AS THE DEIR IMPLIES?

SCENARIO 1.

Using 2010 actual statistics on lifts, the Hobart Yard would lose 59% of its lift capacity by shifting international containers to the SCIG. It would then replace the Hobart with 5% additional international containers. The remaining 41% of the Hobart yard handles domestic and transloaded containers. No information on the splits between domestic and transloaded at Hobart are in the DEIR or seemingly published elsewhere, we have assumed an even split in the two types. Note that BNSF to refer to all of the non-international containers it handles at Hobart as "domestic" containers, even though a good proportion of them are actually "transloaded"). See Table 3 below.

In 2010 there were 1,090,000 "actual" lifts at the Hobart Yard

Table 3. Where containers would go under Scenario 1 – The Hobart Yard, 2010, if SCIG had opened that year (last year with accurate figures for actual lifts, so this is a model)

Actual total lifts in 2010	Int'l lifts gone to SCIG (59%)	Add back 5% international containers as the DEIR states	Pure domestic containers* 41% (remaining space)	Total of pure domestic and 5% inter-national containers
1,090,000 **Note: capacity is 1,500,000**	**643,100**	**54,500**	**** After international containers go to SCIG there would be only "pure domestic" containers at the Hobart, according to the DEIR – these are containers that did not contain goods that originated at the Ports.*** ***That means, 41% of the remaining space at the Hobart yard after removing international containers***	***446,900 54,500 =501,400*** ***501,400*** ***This means the Hobart Yard would be only 33% full if the SCIG had opened in 2010 and if Hobart thereafter handled only pure domestic containers.*** ***That would leave 66% of the capacity EMPTY – or potentially available for 998,600 transloaded***

			would be "pure domestic containers." (If there are even that many to handle at Hobart	***containers (which is not mentioned in the SCIG DEIR).*** ***CAPACITY LEFT AT HOBART FOR 998,600 MORE CONTAINERS IF SCIG OPENED***

*ARB states that Hobart is 41% "domestic containers," including domestic and transloaded.

According to statements in the DEIR, the Hobart Yard will not be handling any international cargo that originated at the Ports if the SCIG opens. Let's accept that as factual for this scenario and see what would happen to the Hobart Yard. If SCIG had opened in 2010, and Hobart's international containers were shifted to SCIG, Hobart Yard would be handling only 33% of the lifts it handled in 2010. If it handled no additional transloaded containers with international cargo that originated at the Ports, it would be two-thirds empty." *(See other scenarios for how quickly it could fill up with transloaded containers).*

This is the ONLY scenario under which trucks from the Ports would be reduced on the I-710 Freeway. That is, for the DEIR to be correct, Hobart would handle only 5% international containers and also "pure" domestic containers with local goods. As the DEIR claims, it would not handle international goods that came in through the ports and were transloaded into 53-foot containers. It would be the largest intermodal rail yard in the U.S. operating 66% empty.

BASED ON FUTURE CARGO FORECASTS, HOW QUICKLY COULD THE HOBART YARD ACTUALLY FILL UP WITH TRANSLOADED AND DOMESTIC CONTAINERS AFTER THE BNSF SCIG OPENS?

SCENARIO 2. Recognizing that transloading as a trend is surging and is currently 25%, where does the 25% of transloaded cargo go? John Doherty, director of the Alameda Corridor Transportation Authority (ACTA) says that ½ of the transloaded cargo goes "east" – to City of Industry, Mira Loma, San Bernardino, etc. He says that the other ½ goes to the rail yards that are "north of the Ports" (UP Commerce, UP LATC and BSNF Hobart).[xvi]

Let's look at forecasts for the year 2016. See below; in 2016 it is estimated that there will be with 17.8 million TEUs at the twin ports. Let's estimate how many transloaded containers there would be and where they could possibly go.

Table from DEIR, below (DEIR, at 1-23). *Note it has inappropriate figures for near/off-dock rail throughput (that is, it does not account for 25% transloading).*

Table 1-5. 2009 San Pedro Bay Ports Direct Intermodal Cargo Forecast.

2009 San Pedro Bay Ports Direct Intermodal Cargo Forecast (shown in Million TEUs)							
Year	2008 (Actual)	2012	2016	2020	2023	2030	2035
Total San Pedro Bay Ports Cargo Volume	14.3	14.3	17.8	21.8	25.2	34.6	43.2
Total Direct Intermodal	6.1 (42.2%)	5.7 (40.0%)	7.1 (40.0%)	8.7 (40.0%)	10.1 (40.0%)	13.8 (40.0%)	17.3 (40.0%)
